been studied in early and established RA in combination with MTX²⁸¹⁻²⁸⁸ (see Figure 61-8). These trials have shown superior improvements in clinical and radiographic end points in the combination groups.^{286,287} Other biologic agents—rituximab, an anti-CD20 monoclonal antibody; abatacept, a T cell co-stimulatory inhibitor; and tocilizumab, an IL-6 receptor antagonist—have been studied in combination with MTX.²⁸⁹⁻²⁹¹ In the REFLEX (Randomized Evaluation of Long-Term Efficacy of Rituximab in RA) trial, rituximab versus placebo was added to baseline MTX in RA patients who were suboptimal responders to MTX with failure of one or more TNF inhibitors.²⁸⁹ Results showed that the combination group had significant improvements in ACR-N responses. Abatacept versus placebo in addition to background MTX was studied in RA patients with a suboptimal response to MTX, and results at 1 year showed significant improvements in clinical and radiographic end points.²⁹⁰ The LITHE (Tocilizumab Safety and The Prevention of Structural Joint Damage) study compared the addition of tocilizumab versus placebo in MTX nonresponders and showed an improvement in structural outcomes at 1 year.²⁹¹ Concerns do exist regarding the risks of infection and infusion reaction in combination therapy that includes biologic agents.

Selecting the Right Patients for Combination Therapy

Factors that predict a poor prognosis for patients with RA are well accepted and include rheumatoid factor, elevated erythrocyte sedimentation rate and C-reactive protein (CRP), the number of joints involved, erosions, and the presence of certain genetic markers. However, unless these factors can be shown to predict response to certain therapies in a differential fashion, they are of limited therapeutic use. Patient characteristics recommending one therapeutic regimen over another remain to be fully elucidated. Genetic differences have been suggested to influence outcomes in a differential fashion. Until this observation can be corroborated and factors that predict response to other therapies elucidated, choices will remain largely empiric.

Treatment of patients with RA using MTX combinations should be the gold standard against which future therapies are compared. Available data demonstrate that a variety of combinations are more effective than MTX alone. Many questions remain to be answered regarding the appropriate timing of combination therapy and the optimal combinations for specific patients and for specific clinical situations (e.g., induction, maintenance therapy, suboptimal response to MTX). Future research is needed to clarify the role of corticosteroids and, particularly, biologic response modifiers (specifically anti-TNF therapies) as components of and alternatives to MTX combination regimens.

Immunosuppressive Drugs

JACOB M. VAN LAAR

KEY POINTS

Immunosuppressive drugs are effective and indispensable as remission inducing and maintenance agents in the management of inflammatory rheumatic conditions. They constitute a heterogeneous group of compounds, each with a unique mode of action and toxicity profile.

The long-term use of immunosuppressive drugs is associated with an increased risk of bacterial, viral, and fungal infection, as well as a reduced response to vaccinations.

Cytostatic agents should be avoided in pregnancy and lactation, and referral to a fertility clinic should be considered for all fertile male and female patients. Other immunosuppressive drugs should only be used in pregnancy if the potential benefits outweigh the potential risks.

Cyclophosphamide is the most commonly used drug for remission induction in severe lupus erythematosus and necrotizing vasculitis. Its toxicities include myelosuppression, infection, ovarian failure, hemorrhagic cystitis, and malignancy including bladder cancer, especially with high cumulative doses.

Azathioprine can be effective as a glucocorticoid-sparing agent in remission maintenance therapy, particularly in systemic lupus erythematosus and necrotizing vasculitis. It can induce severe myelosuppression in patients with low or absent thiopurine methyltransferase (TPMT) activity that is affected by a polymorphism that can be identified by genetic screening. Severe myelosuppression can also occur in patients with normal TPMT activity, and regular monitoring of white blood counts is recommended.

The interaction of azathioprine and allopurinol can lead to fatal myelosuppression and should be avoided.

Cyclosporine can be effective in refractory rheumatoid arthritis, psoriatic arthritis, systemic lupus erythematosus, and inflammatory eye disease. It affects renal function and blood pressure, and dose reduction may be necessary. Drug interactions between cyclosporine and other drugs can result in clinically relevant changes in plasma concentrations of cyclosporine and/or concomitant medication.

Mycophenolate mofetil can be used as a remission induction agent in lupus nephritis and is increasingly used for remission maintenance treatment of systemic lupus erythematosus and necrotizing vasculitis. It is generally well tolerated, although diarrhea and leukopenia may necessitate its discontinuation.

Thalidomide, chlorambucil, sirolimus, and tacrolimus are (rarely) used for specific rheumatologic indications, usually in the event that conventional therapies fail.

Immunosuppressive drugs comprise different classes of drugs that dampen the immune system—notably T and B lymphocytes—functionally and/or numerically (Table 62-1) but do not permanently correct the fundamental imbalance of immune regulation in autoimmune disease. As such, they do not have curative potential yet they can be effective in remission induction and control of specific rheumatic disease manifestations and remain cornerstone drugs in the management of rheumatic conditions. Many immunosuppressive drugs have withstood the test of time, as attested by their ongoing use in transplantation medicine, nephrology, gastroenterology, ophthalmology, dermatology, and rheumatology. Consequently, their therapeutic potential and toxicity profiles hold few surprises. Apart from drug-specific toxicities, the main risk of immunosuppressive treatment is infection. In the absence of validated biomarkers of infection, sound clinical judgment and experience remain indispensable in monitoring patients who use immunosuppressive drugs, often for long periods of time. The use of live vaccines is contraindicated, and although other vaccinations are generally less effective, annual influenza vaccination is recommended in patients taking immunosuppressive medication.

This chapter outlines the clinical pharmacology and therapeutic use of immunosuppressive drugs used in rheumatology. These include cytostatic agents that affect bone marrow progenitor cells (cyclophosphamide, chlorambucil, and azathioprine) and drugs such as cyclosporine, sirolimus, tacrolimus, and mycophenolate mofetil (MMF) that target lymphocytes by inhibiting specific intracellular signaling pathways and/or proliferation. Their effects on the immune system overlap with those of traditional disease-modifying antirheumatic drugs such as methotrexate, glucocorticoids, and the newer biologics. Thalidomide is also discussed in this chapter, although its therapeutic utility is limited. The most commonly used immunosuppressive drugs—cyclophosphamide, azathioprine, and MMF—are discussed in more detail. Glucocorticoids, methotrexate, leflunomide, and biologic agents are discussed elsewhere.

ALKYLATING AGENTS

Alkylating agents substitute alkyl radicals into deoxyribonucleic acid (DNA), which ultimately results in cell death. Cyclophosphamide was introduced as an antitumor agent in 1958 and is still one of the most widely administered anticancer agents and one of the most potent immunosuppressants. It is the drug of choice for remission induction therapies in severe systemic lupus erythematosus (SLE) and necrotizing vasculitis. Chlorambucil is rarely used in

Table 62-1 Mechanisms of Action of Immunosuppressive Drugs

Drugs	Class	Mechanism of Action
Cyclophosphamide, chlorambucil	Alkylating cytotoxics	Active metabolites alkylate DNA
Azathioprine, mercaptopurine	Purine analogue cytotoxics	Inhibit purine synthesis
Cyclosporine, tacrolimus (FK506)	Calcineurin inhibitors	Inhibit calcium-dependent T cell activation and interleukin-2 production
Sirolimus (rapamycin)	Noncalcineurin-binding macrolide immunoregulator	Blocks interleukin-2-mediated and growth factor-mediated signal transduction
Mycophenolate mofetil	Purine synthesis inhibitor	Mycophenolic acid inhibits inosine monophosphate dehydrogenase
Thalidomide	Glutamic acid derivative	Inhibition of tumor necrosis factor production and angiogenesis

rheumatology in current practice but can be considered a therapeutic option in patients who experience serious side effects on cyclophosphamide.

Cyclophosphamide

Structure

Cyclophosphamide is an oxazaphosphorine-substituted nitrogen mustard and inactive prodrug requiring enzymatic bioactivation (**Figure 62-1**). Cyclophosphamide is the alkylating agent of choice for most rheumatic disease requiring such therapy.

Mechanisms of Action

Its DNA-alkylating effects are mediated predominantly through phosphoramidate mustard and, to a lesser extent, other active metabolites. These positively charged, reactive intermediates alkylate nucleophilic bases, resulting in the cross-linking of DNA and of DNA proteins, breaks in DNA, and consequently decreased DNA synthesis and apoptosis.¹ The cytotoxicity of alkylating agents correlates with the amount of DNA cross-linking, but the relationship between cytotoxicity and immunosuppressive effects is unclear. The effects of cyclophosphamide are not exclusively limited to proliferating cells or particular cell types. Sensitivity varies among cell populations, however; for example, hematopoietic progenitor cells are relatively resistant to even high doses of cyclophosphamide. The immunosuppressive effects of cyclophosphamide include decreased numbers of T lymphocytes and B lymphocytes, decreased lymphocyte proliferation, decreased antibody production, and suppression of delayed hypersensitivity to new antigens with relative preservation of established delayed hypersensitivity.²

Pharmacology

Absorption and Distribution. Oral and intravenous (IV) administration of cyclophosphamide results in similar plasma concentrations.³ Peak plasma concentrations of cyclophosphamide occur 1 hour after oral administration. Protein binding of cyclophosphamide is low (20%), and it is widely distributed.¹

Metabolism and Elimination. Cyclophosphamide is rapidly metabolized, largely by the liver, to active and inactive metabolites. The formation of the active 4-hydroxycyclophosphamide is mediated by various cytochrome P-450 (CYP) enzymes, and genetic variations in the enzymes in lupus nephritis patients have been shown to affect responses to cyclophosphamide.⁴ 4-Hydroxycyclophosphamide, which is not cytotoxic at physiologic pH, readily diffuses into cells and spontaneously decomposes into the active phosphoramidate mustard. The elimination half-life of cyclophosphamide is 5 to 9 hours, and alkylating activity is undetectable in the plasma of most patients 24 hours after a dose of 12 mg/kg.¹ Plasma concentrations of cyclophosphamide are not clinically useful predictors of either efficacy or toxicity. Between 30% and 60% of the total cyclophosphamide is eliminated in the urine, mostly as inactive metabolites, although some cyclophosphamide and active metabolites such as phosphoramidate mustard and acrolein can also be detected in urine.¹

Pharmacokinetic Considerations in Special Circumstances

Liver Disease. Although the half-life of cyclophosphamide is increased to 12 hours in patients with liver failure compared with 8 hours in controls, toxicity is not increased, suggesting that exposure to cytotoxic metabolites is not increased and dose modification in liver disease is generally not required.¹

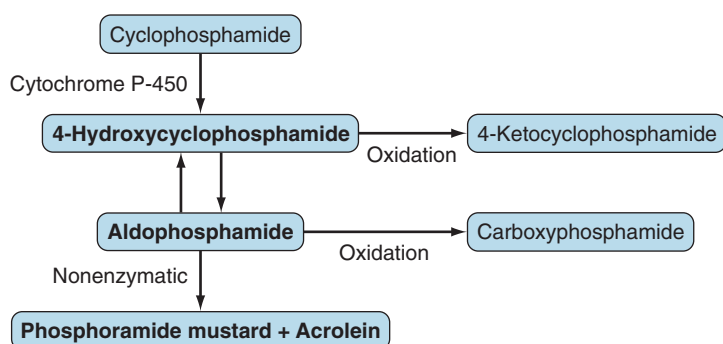

Figure 62-1 The metabolism of cyclophosphamide. Cyclophosphamide is converted to 4-hydroxycyclophosphamide, in equilibrium with its tautomer aldophosphamide, by cytochrome P-450 enzymes. Subsequent nonenzymatic processes lead to the formation of phosphoramidate mustard and acrolein. Oxidation of 4-hydroxycyclophosphamide and aldophosphamide through enzymes including aldehyde dehydrogenase results in inactive metabolites. Cytotoxic metabolites are shown in bold type.

Renal Impairment. Some studies have shown little alteration in drug disposition with no increased toxicity in patients with impaired renal function.¹ In patients with autoimmune disease and a creatinine clearance of 25 to 50 mL/min and 10 to 25 mL/min, exposure to cyclophosphamide increased approximately 40% and 70%, respectively.⁵ In clinical practice, initial cyclophosphamide doses are therefore decreased by approximately 30% in patients with moderate-to-severe renal impairment and subsequent doses are titrated according to clinical response and effects on the leukocyte (white blood cell) count. Cyclophosphamide is removed by dialysis and is administered after dialysis, or, alternatively, dialysis can be initiated the day after cyclophosphamide administration.⁵

Clinical Indications

Cyclophosphamide remains the drug of choice for most patients with systemic necrotizing vasculitis or Goodpasture's syndrome, for many patients with organ-threatening SLE, and for some patients with autoimmune disease-associated interstitial lung disease and inflammatory eye disease. In rheumatoid arthritis (RA) unless complicated by vasculitis, less toxic and more effective drugs have replaced cyclophosphamide. In SLE a remission induction course with IV cyclophosphamide followed by maintenance with azathioprine or mycophenolate to minimize cyclophosphamide toxicity is the most commonly used treatment for severe organ involvement including lupus nephritis, although remission induction regimens with MMF have been propagated as an effective and safe alternative for cyclophosphamide (discussed later). The original National Institutes of Health (NIH) protocol involved 6 monthly IV infusions with cyclophosphamide 1 g/m² then once every 3 months for at least 24 additional months,⁶ whereas the Euro-Lupus protocol used in Europe involved administration of six IV infusions of 500 mg of cyclophosphamide every 2 weeks followed by azathioprine maintenance (Table 62-2). A comparison with 6 monthly IV infusions with cyclophosphamide 500 mg/m², followed by two further infusions of slightly higher doses 3 and 6 months later, and azathioprine maintenance therapy resulted in similar rates of the end points of end-stage renal disease or doubling of creatinine concentration with up to 10 years of follow-up.⁷ Cyclophosphamide as either IV pulse therapy or orally can also be effective in patients with other serious complications of SLE including central nervous system involvement and thrombocytopenia and interstitial lung disease associated with systemic sclerosis and other autoimmune diseases.⁸⁻¹⁰ Several trials have investigated whether IV cyclophosphamide is as effective as oral cyclophosphamide as remission induction therapy for granulomatosis with polyangiitis (GPA), the newly proposed name for Wegener's granulomatosis.¹¹ Although early trial results suggested superiority of oral dosing, more recent clinical trial data pointed to equal efficacy, but slightly less hematologic toxicity with IV therapy.¹²⁻¹⁴ As in lupus nephritis, shorter induction courses of cyclophosphamide have been reported to be effective in GPA and microscopic polyangiitis.¹⁵ Cyclophosphamide has a steep dose-response curve, making it an ideal compound for dose escalation. High doses of cyclophosphamide, with or without stem cell rescue and lymphoablative antibodies

Table 62-2 Lupus Nephritis Treatment Protocols

National Institutes of Health Protocol
Cyclophosphamide: 6× monthly IV 500-750 mg/m ² , then maintenance doses every 3 mo until 1 yr after remission, or consider alternative remission maintenance treatment with azathioprine or mycophenolate mofetil. Dose adjustments on the basis of nadir leukocyte counts and glomerular filtration rate. All patients to receive prednisone 0.5-1 mg/kg/day for 4 wk, decreasing the every-other-day dose each week, if possible, by 5 mg to achieve a prednisone dose of 0.25 mg/kg on alternate days.
Euro-Lupus Protocols
Low-dose cyclophosphamide: 6× biweekly IV 500 mg High-dose cyclophosphamide: 6× monthly IV 500 mg/body surface area monthly, followed by 2 quarterly pulses with higher dose (+250 mg depending on leukocyte nadir, max 1500 mg) All patients to receive: Glucocorticoids: 3× daily IV 750 mg methylprednisolone, followed by oral 0.5-mg equivalent prednisolone/kg/day for 4 wk. After 4 wk, tapering of glucocorticoid by 2.5 mg prednisolone every 2 wk. Low-dose glucocorticoid therapy (5-7.5 mg prednisolone/day) was maintained at least until mo 30 after inclusion. Dose at discretion of treating physician thereafter. Azathioprine: oral 2 mg/kg daily starting 2 wk after last cyclophosphamide infusion until mo 30 after inclusion. Choice of immunosuppressant at discretion of treating physician thereafter.

IV, intravenous.

or total body irradiation, have been used for severe juvenile idiopathic arthritis (JIA), RA, systemic sclerosis, and SLE.¹⁶ With the introduction of effective biologics and new treatment paradigms for RA and JIA, the clinical need for immunoablative treatment in these diseases has waned. Although large series have shown promising results of immunoablative therapy and stem cell rescue in patients with severe SLE, a recent randomized trial showed that standard-dose IV cyclophosphamide was not inferior to high-dose cyclophosphamide without stem cell rescue or lymphoablative antibodies.¹⁷ Prospective, randomized trials are in progress in systemic sclerosis to compare safety and efficacy of IV pulse cyclophosphamide and immunoablative therapy with stem cell rescue.

Dosage and Route of Administration

Typical dosage regimens are presented in Table 62-2. Dosages for IV pulse therapy with cyclophosphamide range from 0.5 to 1 g/m² and for oral therapy 2 mg/kg. The bioavailability of oral cyclophosphamide is excellent.

Toxicity

Hematologic. Reversible myelosuppression manifesting as leukopenia and neutropenia is common and dose dependent. Generally, platelet counts are not affected with IV pulse doses of less than 50 mg/kg, but with long-term oral use, a mild decrease in platelet count is common. After a single IV dose of cyclophosphamide, the approximate times to nadir and recovery of leukocyte counts are 8 to 14 days and 21 days, respectively.¹⁸ The white blood cell nadir is about 3000 cells/mm³ after a dose of 1 g/m² (≈25 mg/kg) and 1500 cells/mm³ after a dose of 1.5 g/m². With long-term use,

there is increased sensitivity to the myelosuppressive effects of cyclophosphamide and doses usually need to be decreased over time.

Infection. Infection with a range of common and opportunistic pathogens is a frequent complication. In 100 patients with SLE, infection occurred in 45 patients during treatment with a cyclophosphamide-based regimen and was the primary cause of death in 7 patients.¹⁹ In this study, infection was equally common in patients receiving oral or IV cyclophosphamide and was associated with a white blood cell nadir at some point in treatment of less than 3000/mm³ (55% infection rate vs. 36%). At the time of infection, the average white blood cell count was normal, however.¹⁹ A higher maximal corticosteroid dose was also associated with increased risk of infection. Half of the infections occurred at prednisone doses of less than 40 mg/day, and a quarter of the infections occurred at doses less than 25 mg/day. Lower rates of infection (25% to 30%) have been reported in SLE patients receiving cyclophosphamide in National Institutes of Health (NIH) protocols.²⁰ Oral cyclophosphamide regimens generally pose a greater risk of infection than IV pulse regimens. Serious infections occurred in 41% and 70% of patients with GPA treated with pulse IV and daily oral cyclophosphamide, respectively.¹² These rates of infection are higher than rates reported in long-term NIH protocols, in which 48% of 158 patients experienced 140 infections requiring hospitalization.²¹ The reported frequency of cyclophosphamide-associated infection varies, probably as a function of the stage and severity of the underlying disease, the degree of cyclophosphamide-induced immunosuppression, and variations in concomitant glucocorticoid regimens. *Pneumocystis jiroveci* pneumonia has been recognized as a preventable, serious opportunistic infection that complicates treatment of systemic vasculitis with regimens using cyclophosphamide and methotrexate. The risk is highest during the remission induction phase and is greater with oral than IV cyclophosphamide regimens.²² Surprisingly, in two placebo-controlled, randomized clinical trials in scleroderma lung disease, active treatment for 1 year with either oral cyclophosphamide or sequential treatment with prednisolone plus IV cyclophosphamide followed by azathioprine was not associated with more toxicity, however, suggesting disease-specific differences in toxicity.^{9,10}

Urologic. The bladder toxicities of cyclophosphamide, hemorrhagic cystitis, and bladder cancer are related to route of administration, duration of therapy, and cumulative cyclophosphamide dose. Bladder toxicity, a particular problem with long-term oral cyclophosphamide, is largely due to acrolein, a metabolite of cyclophosphamide. It is commonly accepted that bladder toxicity can be minimized in patients receiving pulse doses of IV cyclophosphamide by administering mesna, a sulfhydryl compound that binds acrolein in the urine and inactivates it.²³ Direct evidence for the effectiveness of mesna in preventing cystitis, however, comes from its use with ifosfamide in patients with cancer and data from animal models. The data from rheumatology series are consistent with a protective effect but are inadequate to come to firm conclusions, which explains differences between national guidelines.²⁴ The short half-life of mesna renders it suboptimal for the prevention of bladder

toxicity in patients receiving daily oral cyclophosphamide—but oral mesna administered three times a day with daily oral cyclophosphamide decreased the incidence of bladder toxicity to 12%.²⁵

Nonglomerular hematuria, which may range from minor, microscopic blood loss to severe, macroscopic bleeding, is the most common manifestation of cyclophosphamide-induced cystitis.²⁶ Nonglomerular hematuria occurred at some time in 50% of 145 patients treated with oral cyclophosphamide and was related to the duration of therapy and cumulative cyclophosphamide dose.²⁶ The risk of bladder cancer was increased 31-fold (95% confidence interval [CI], 13-fold to 65-fold), and 7 patients (5%) had developed bladder cancer anytime between 7 months and 15 years after initiating therapy. The cancer was preceded by nonglomerular hematuria in all patients. Six of the seven patients had a cumulative dose of more than 100 g of cyclophosphamide and a duration of therapy of more than 2.7 years. Smokers were at increased risk of hemorrhagic cystitis and bladder cancer.

Malignancy. Cyclophosphamide increases the risk of malignancies (other than bladder cancer) twofold to fourfold. In the largest study, 119 patients with RA who had been treated with oral cyclophosphamide were followed for 20 years.²⁶ There were 50 cancers in 37 patients in the cyclophosphamide group compared with 26 cancers in 25 of 119 control RA patients. Bladder, skin, myeloproliferative, and oropharyngeal malignancies occurred more commonly in the cyclophosphamide group. The risk of malignancies increased with the cumulative dose of cyclophosphamide, and 53% of patients who received more than 80 g of cyclophosphamide developed malignancy. Few malignancies have been reported in patients treated with pulse IV cyclophosphamide regimens. Current data do not allow quantification of the long-term risk of malignancy associated with pulse IV cyclophosphamide treatment, but it is likely to be substantially smaller than that associated with oral regimens.

Reproductive. Cyclophosphamide, as used in autoimmune disease, results in significant gonadal toxicity. The risk of sustained amenorrhea after cyclophosphamide therapy has ranged from 11% to 59%.²⁷ The risk of ovarian failure depends more on age of the patient and cumulative dose of cyclophosphamide than on route of administration.²⁷ Patients younger than 25 years old receiving 6 pulses of IV cyclophosphamide had a low frequency of ovarian failure (none of four patients), whereas patients older than 31 years receiving 15 to 24 pulses all had ovarian failure (four of four patients). The use of alkylating agents in male patients leads to azoospermia, and, if the clinical situation allows, referral to a fertility clinic for banking of sperm (or ova in female patients) should be considered before cyclophosphamide treatment. There was no increase in genetic disease in the offspring of adults who underwent cancer chemotherapy in childhood.²⁸

Pulmonary. Cyclophosphamide-induced pulmonary toxicity occurs in less than 1% of patients. Early-onset pneumonitis 1 to 6 months after exposure to cyclophosphamide may respond to withdrawal of the drug and treatment with corticosteroids. A more insidious, irreversible, late-onset pneumonitis and fibrosis with radiographic findings of

diffuse reticular or reticulonodular infiltrates may occur after treatment with oral cyclophosphamide for 1 to 13 years.²⁹

Miscellaneous. A varying degree of reversible alopecia can occur with daily oral and monthly pulse cyclophosphamide. Cardiotoxicity, a dose-limiting adverse effect in oncology, and water intoxication, owing to inappropriate antidiuretic hormone secretion, are rare at standard doses.³⁰ Unusual hypersensitivity reactions include urticaria and anaphylaxis, although the bladder protectant mesna is a more likely cause of allergic responses in patients receiving both drugs.^{31,32}

Strategies to Minimize Toxicity. Strategies to minimize toxicity include adjusting the dose of cyclophosphamide to avoid a significant degree of leukopenia (white blood cell count $<3000/\text{mm}^3$ for daily oral therapy or a nadir of $<2000/\text{mm}^3$ for pulse IV therapy) and granulocytopenia.³³ The blood count is monitored initially at 1- to 2-week intervals and monthly thereafter in patients on stable oral doses. To decrease the risk of infection added by concomitant high-dose corticosteroids, the dose of corticosteroids should be reduced after a clinical response has been obtained. Alternate-day glucocorticoids can be considered in the maintenance phase. Oral cyclophosphamide is best administered as a single dose in the morning with the patient drinking plenty of fluids and emptying the bladder frequently to dilute the urinary concentration of acrolein and to minimize the time the bladder is exposed to it. Prophylaxis against *P. jiroveci* pneumonia is often prescribed, particularly during the induction phase when doses of cyclophosphamide and corticosteroids are higher. The use of mesna to prevent bladder toxicity is described earlier. Urinalysis should be performed monthly, and nonglomerular hematuria should be evaluated by a urologist. All patients who receive cyclophosphamide, particularly patients who develop hemorrhagic cystitis, are at increased risk of developing bladder cancer, and lifelong surveillance is required with urinalysis, urine cytology, and, if indicated, cystoscopy.³⁴ Lastly, drugs that are less toxic than cyclophosphamide such as methotrexate and MMF are an option for inducing remission or remission maintenance in patients with GPA or lupus nephritis.^{35,36}

Pregnancy and Lactation

Cyclophosphamide is a U.S. Food and Drug Administration (FDA) Pregnancy Category D drug. Cyclophosphamide is teratogenic, particularly in the first trimester, and should be avoided in pregnancy and during lactation.^{37,38} If a patient becomes pregnant while taking (receiving) this drug, the patient should be apprised of the potential hazard to the fetus. Women of childbearing potential should be advised to avoid becoming pregnant.

Drug Interactions

Cimetidine inhibits the activity of several hepatic enzymes. It has resulted in increased exposure to cyclophosphamide metabolites in a rabbit model.³⁹ *Ranitidine* and presumably other H_2 -receptor antagonists that have little effect on hepatic drug metabolism are not associated with increased

cyclophosphamide toxicity.⁴⁰ *Allopurinol* increases the half-life of cyclophosphamide and the frequency of leukopenia.⁴¹ Cyclophosphamide decreases plasma pseudocholinesterase activity and can potentiate the effect of *succinylcholine*.⁴²

Chlorambucil

Structure

Chlorambucil (4(4-bis(2-chloroethyl)aminophenyl)-butyric acid) has occasionally been used as an alternative to cyclophosphamide in some rheumatologic diseases, but its clinical utility is limited now that effective immunosuppressive drugs and biologics with more favorable safety profiles are available.

Mechanism of Action

The mechanism of action of chlorambucil is similar to that of cyclophosphamide, but slower.

Pharmacology

Chlorambucil is well absorbed ($>70\%$) after oral administration with peak concentrations occurring within 2 hours.⁴³ Chlorambucil is extensively metabolized by β oxidation to a metabolite, phenylacetic acid mustard, which is also cytotoxic.^{43,44} Less than 1% of the oral dose of chlorambucil appears in the urine as unchanged drug.⁴¹ The plasma half-life of chlorambucil and the phenylacetic acid mustard metabolite is 30 to 180 minutes.^{43,44}

Clinical Indications

Chlorambucil can be effective for patients with inflammatory eye disease including Behçet's syndrome^{45,46} and occasionally for refractory dermatomyositis.⁴⁷ Chlorambucil is used as an alternative alkylating agent for patients unable to tolerate cyclophosphamide because of bladder toxicity or gastrointestinal intolerance. Chlorambucil does not seem to be as effective as cyclophosphamide, however, in the treatment of vasculitis or glomerulonephritis, or systemic sclerosis. The use of chlorambucil in RA is obsolete given the availability of a multitude of alternative drugs with a more favorable risk-benefit profile.

Dosage

Chlorambucil is often started at an oral dose of 0.1 mg/kg/day; the dose is increased or decreased according to clinical response and toxicity. Doses of 0.2 mg/kg/day or greater are associated with more frequent myelosuppression. Alternatively, a "start-low, go-slow" approach, with chlorambucil started at a dose of 4 mg/day and increased in 1-mg increments at 1- to 2-month intervals, if required, may be better tolerated. Even with this approach, 75% of patients discontinued therapy because of chlorambucil-related toxicity.⁴⁸ Regular monitoring, particularly of the white blood cell count, at approximately 2-week intervals initially, and then monthly when stable, is required.

Toxicity

Hematologic. Myelosuppression is common and may be abrupt in onset. The degree of leukopenia and neutropenia is dose related, but there are considerable interindividual differences in sensitivity. Myelosuppression is usually reversible; however, it may take several months for the white blood cell count to return to the normal range, and some patients remain relatively leukopenic. Irreversible, fatal bone marrow suppression has been reported in patients receiving chlorambucil for rheumatic disease.⁴⁸

Infection. The average frequency of herpes zoster infection is 13%. As is the case with cyclophosphamide, infections resulting from a wide range of bacterial and nonbacterial pathogens occur.⁴⁸

Malignancy. Treatment with chlorambucil increases the risk of leukemia, particularly myeloid leukemia, and has been associated with a range of lymphomas.^{48,49} Various solid organ tumors have occurred in association with chlorambucil, but no causal relationship has been established.⁴⁸

Miscellaneous. Other adverse effects of chlorambucil include azoospermia and amenorrhea, which are usually reversible. Pulmonary fibrosis, oral ulceration, hepatotoxicity, nausea, fever, and rashes are other adverse effects.

Pregnancy and Lactation

Chlorambucil is an FDA Pregnancy Category D drug. It should not be used in pregnancy or lactation. Chlorambucil can cause fetal harm when administered to a pregnant woman. If a patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus. Women of childbearing potential should be advised to avoid becoming pregnant.

PURINE ANALOGUES

Azathioprine

Structure

Azathioprine is a prodrug that is converted to 6-mercaptopurine involving the removal of an imidazole group.⁵⁰ 6-Mercaptopurine is a purine analogue that acts as a cycle-specific antimetabolite chemotherapeutic agent interfering with the synthesis of nucleotides, thereby inhibiting proliferation of lymphocytes. Azathioprine has a better therapeutic index than 6-mercaptopurine and has replaced it in the treatment of rheumatic autoimmune disease.

Mechanisms of Action

The exact mechanism of action of the active thiopurine metabolites of azathioprine in autoimmune disease is unknown. Thiopurine metabolites such as thioguanine nucleotides decrease the *de novo* synthesis of purine nucleotides by inhibiting amidotransferase enzymes and purine ribonucleotide interconversion and are incorporated into DNA and ribonucleic acid (RNA).⁵⁰ The incorporation of thioguanine nucleotides into the nucleic acids of cells is thought to mediate the cytotoxicity of azathioprine, whereas inhibition of purine synthesis may be more important in decreasing cellular proliferation. Leukopenia is unnecessary for immunosuppression. Azathioprine decreases the circulating lymphocyte count, suppresses lymphocyte proliferation, inhibits antibody production, inhibits monocyte production, suppresses natural killer cell activity, and inhibits cell-mediated and humoral immunity.

Pharmacology

Absorption and Distribution. Oral azathioprine is well absorbed and rapidly converted to 6-mercaptopurine, which is further metabolized to several compounds including 6-thiourate (Figure 62-2) that are excreted in urine. The plasma half-life of azathioprine is less than 15 minutes but it is 1 to 3 hours for the active derivative, 6-MP.⁵¹ The bioavailability of azathioprine, measured as the concentrations of mercaptopurine achieved after oral administration, varies. In healthy volunteers, bioavailability ranged from 27% to 83% with an average of 47%.⁵¹ Mercaptopurine is widely distributed with a volume of distribution of 4 to 8 L/kg.⁴⁹

Metabolism and Elimination. The metabolism of azathioprine is complex^{50,52} and has been simplified in Figure 62-2. Two enzymes, xanthine oxidase and thiopurine methyltransferase (TPMT), shunt mercaptopurine metabolites to relatively inactive compounds, whereas other enzymes such as hypoxanthine-guanine-phosphoribosyl-transferase lead to the formation of cytotoxic thiopurine nucleotides. Low TPMT activity or inhibition of xanthine oxidase by drugs such as allopurinol leads to decreased detoxification and increased formation of cytotoxic metabolites after the administration of azathioprine or mercaptopurine. Maximal concentrations of mercaptopurine occur 1 to 3 hours after administration of azathioprine, and the half-life of mercaptopurine is 1 to 2 hours.⁵¹ The half-life of the intracellular, active 6-thioguanine nucleotides is estimated to be 1 to 2

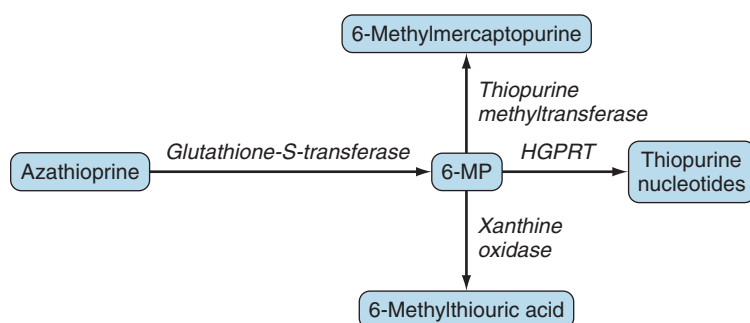

Figure 62-2 Azathioprine is converted to mercaptopurine (6-MP) enzymatically by glutathione-S-transferase and nonenzymatic mechanisms. Xanthine oxidase and thiopurine methyltransferase metabolize 6-MP to the inactive metabolites 6-methylthiouric acid and 6-methylmercaptopurine. Hypoxanthine-guanine-phosphoribosyl-transferase (HGPRT) metabolizes 6-MP to active, cytotoxic thiopurine nucleotides.

weeks, however, and concentrations do not change over the 24-hour dose period in patients receiving daily azathioprine.⁵³ At conventional rheumatologic doses, approximately 1% of mercaptopurine is excreted unchanged in the urine.⁵³ Increased toxicity can occur with renal impairment (creatinine clearance <25 mL/min), and a modest dose reduction is usually necessary. The substantial interindividual variability in azathioprine disposition and TPMT activity are more important determinants of sensitivity to azathioprine than renal function.⁵⁴ Azathioprine is only slightly dialyzable (10%) through conventional hemodialysis membranes.

Dosage

Azathioprine is often started at a dose of 1 mg/kg daily, and if this is tolerated, the dose is increased to 2 to 2.5 mg/kg after 2 to 4 weeks. A gradual increase in dose is often better tolerated. The onset of immunosuppressive effects is relatively slow, over several weeks, presumably because the active thioguanine metabolites slowly accumulate intracellularly.

Clinical Indications

In current practice, azathioprine is mainly used in the treatment of connective tissue disease rather than inflammatory joint disease. In RA azathioprine is less effective than methotrexate and has a slow mode of onset when compared with other disease-modifying antirheumatic drugs and biologics. Nevertheless, it remains a treatment option for RA patients with refractory disease or as a corticosteroid-sparing agent in those with organ involvement. Azathioprine is used to treat some patients with lupus nephritis, and although it is more effective than corticosteroids alone, it is not as effective as IV pulse cyclophosphamide to induce remission.⁵⁵ It is effective in maintenance therapy, however,⁵⁶ even after low-dose cyclophosphamide induction. For other manifestations of SLE including cutaneous disease, azathioprine is widely used as a glucocorticoid-sparing agent.⁵⁷ Azathioprine in combination with corticosteroids is useful in the treatment of a range of other autoimmune diseases including inflammatory muscle disease, inflammatory eye disease including Behçet's syndrome,⁵⁸ psoriatic arthritis,⁵⁹ reactive arthritis, and various forms of vasculitis. In systemic vasculitis, azathioprine is less effective as a remission-induction agent than cyclophosphamide¹⁵ but safer as a remission-maintenance and glucocorticoid-sparing drug.³⁷ A small study has shown efficacy, however, of high-dose (1200- to 1800-mg infusions) monthly azathioprine as initial treatment of GPA and lupus nephritis.⁶⁰ Azathioprine is frequently used in systemic sclerosis and overlap syndromes, especially in those with interstitial lung disease or joint involvement.^{10,61}

Toxicity

Hematologic. Reversible myelosuppression is dose related but varies among individuals. Low-dose azathioprine (1 to 2 mg/kg/day) rarely results in leukopenia or thrombocytopenia. Pure red cell aplasia is also rare. Severe myelosuppression is uncommon and caused by low or absent

TPMT activity. Decreased TPMT activity leads to a decreased ability to detoxify mercaptopurine and results in increased formation of cytotoxic thioguanine metabolites and clinical toxicity.⁶² TPMT activity is polymorphic with a trimodal distribution. Approximately 90% of subjects show high activity, 10% show intermediate activity, and 0.3% (the subjects homozygous for the poorly functional polymorphisms) show very low activity.^{62,63} The median TPMT activity in African-Americans is approximately 17% lower than in white Americans.⁶³ The 1 in 300 subjects with low or absent TPMT activity is at great risk of severe azathioprine-induced myelosuppression, which has a delayed but sudden onset, most commonly 4 to 10 weeks after azathioprine has been started.⁶⁴ More than half of all cases of leukopenia in patients receiving azathioprine have a normal TPMT genotype and phenotype, however.

Gastrointestinal. Liver test abnormalities occur in 34% but are seldom serious. Serious liver toxicity, severe cholestasis, hepatic veno-occlusive disease, and nodular regenerative hyperplasia and pancreatitis are rare.

Malignancy. Data regarding the risk of malignancy in patients treated with azathioprine for rheumatologic disease are conflicting. Some studies found an increased risk, particularly of lymphoproliferative malignancies, whereas others did not.⁶⁵ A 24-year retrospective study of 358 SLE patients found no difference in malignancy rates between patients who had received azathioprine and patients who had not, and there were no lymphomas in the azathioprine group.⁶⁶

Azathioprine Hypersensitivity. Acute hypersensitivity syndromes, usually occurring within 2 weeks of starting therapy, with a range of manifestations including shock, fever, rash, pancreatitis, renal failure, and hepatitis are rare.⁶⁷

Others. Infection is less common with azathioprine than with alkylating agents; however, infections with a range of bacterial and nonbacterial pathogens including herpes zoster and cytomegalovirus may occur. The rate of infection when azathioprine is administered alone or with low doses of glucocorticoids is approximately 2.5 per 100 person-years of exposure. Maculopapular or urticarial rashes can occur. Eosinophilia and drug fever are rare.

Strategies to Minimize Toxicity. TPMT activity testing is the most commonly used method to identify patients at risk of serious toxicity. More than 23 variants in the TPMT gene, associated with decreased TPMT activity, have been identified, with the TPMT*2, TPMT*3A, and TPMT*3C alleles accounting for most of the intermediate- or low-activity cases. The concordance between TPMT genetics and phenotypes is slightly less than 100%. TPMT activity (phenotype) can be measured directly in red blood cell membranes. Alternatively (e.g., in patients who have undergone blood transfusions), genetic polymorphisms can be identified by polymerase chain reaction. Guidelines for TPMT activity testing vary among different specialties, but it is generally recommended to test TPMT status before starting azathioprine therapy. Whether testing is cost-effective and clinically useful when compared with traditional monitoring of white blood counts is still a matter of debate.⁶⁸⁻⁷¹ In the absence of TPMT testing, a low initial dose and careful monitoring of the white blood cell count in patients starting azathioprine is required. Some authors

suggest weekly monitoring during the first 15 weeks of azathioprine treatment.⁶⁴ When patients are on a stable dose of azathioprine, blood counts are monitored monthly and liver function tests are monitored every 3 to 4 months.

Drug Interactions

One of the most important, and potentially fatal, drug interactions in rheumatology is the ability of *allopurinol*, through inhibition of xanthine oxidase-mediated inactivation of mercaptopurine, to increase dramatically the cytotoxic effects of azathioprine and mercaptopurine.⁷² Various strategies have been employed to treat hyperuricemia and gout in patients receiving azathioprine, a common clinical problem after transplantation. Reduction of the dose of azathioprine by at least two thirds in patients who also are receiving allopurinol is advocated. Because myelosuppression can still occur after a 75% reduction in dose, however, careful monitoring is required.⁷² Alternatively, uricosurics such as benzbromarone have been effective and safe,⁷² and MMF has been substituted for azathioprine as an alternative immunosuppressant.⁷³ Combination of azathioprine with several other drugs may also increase the risk of myelosuppression: sulfasalazine, ganciclovir, angiotensin-converting enzyme (ACE) inhibitors, carbamazepine, co-trimoxazole, and clozapine. Azathioprine has been associated with resistance to *warfarin* in case reports.⁷⁴

Pregnancy and Lactation

Azathioprine is an FDA Pregnancy Category D drug. Azathioprine and mercaptopurine cross the placenta, but drug and metabolite concentrations are lower in the fetal circulation, suggesting placental metabolism.^{38,75} There are limited data in rheumatologic diseases, and although it is being used in pregnancy, azathioprine is better avoided in pregnancy and lactation if possible.⁷⁶ In a prospective observational study in 189 pregnant women treated with azathioprine for various autoimmune conditions, the rate of major malformation was 3.5%, which was similar to the general population.⁷⁷ Its use was associated with prematurity, however. Azathioprine may be considered in cases where the benefits of disease control in the mother give the best chances of term pregnancy and fetal survival.

CYCLOSPORINE, TACROLIMUS (FK506), AND SIROLIMUS (RAPAMYCIN)

Cyclosporine

Structure

Cyclosporine is a lipophilic endecapeptide derived from a fungus; it is effective in refractory RA, psoriatic arthritis, systemic lupus erythematosus, and autoimmune eye disease.

Mechanism of Action

Cyclosporine impairs production of interleukin-2 and other cytokines, reducing lymphocyte proliferation. Cyclosporine complexes with cyclophilin, one of a group of cytosolic-binding proteins known as *immunophilins*. This complex

binds to and inhibits calcineurin, a serine/threonine phosphatase. Inhibition of calcineurin phosphatase activity prevents the translocation of cytosolic nuclear factor of activated T cells to the nucleus, a translocation that is required for the transcription of genes for cytokines such as interleukin-2 and for T cell activation (Figure 62-3).^{78,79}

Pharmacology

There are two formulations of cyclosporine for oral use: (1) the older, oil-based Sandimmune formulation and (2) the newer, microemulsion Neoral formulation. The active drug, cyclosporine, is identical in both formulations, but the microemulsion formulation results in better bioavailability and less intersubject and intrasubject variability. Neoral or equivalent generic formulations are replacing the Sandimmune formulation of cyclosporine, which is no longer universally available.

Absorption and Distribution. Cyclosporine is poorly and variably absorbed from the gut with a bioavailability of approximately 30%. A high-fat meal increases absorption. There is substantial interindividual (threefold) and intraindividual (twofold) variability in cyclosporine disposition.⁸⁰ The time to peak concentration (1 to 8 hours) and the elimination half-life (3 to 20 hours) vary. Cyclosporine is lipophilic and widely distributed in body tissues, particularly in the lean body mass.⁸⁰ Higher concentrations of cyclosporine are found in red blood cells than in plasma, and whole-blood concentrations are used for monitoring, although this is seldom required in autoimmune diseases. The time to maximal concentration is approximately 25% shorter, and the maximal cyclosporine concentration and area under the concentration curve are increased by approximately 50% with the microemulsion formulation.^{81,82} Also, interindividual and intraindividual variability in cyclosporine disposition is decreased by approximately 50% with the microemulsion formulation.^{81,82}

Metabolism and Elimination. There are two major determinants of cyclosporine disposition. First, P-glycoprotein (Pgp), a drug efflux pump, pumps substrates such as cyclosporine out of cells. Pgp, the product of the multidrug resistance gene, is expressed on intestinal epithelial cells and in the liver. Second, cyclosporine is extensively metabolized by the CYP3A enzyme system, which is active not only in the liver but also in intestinal epithelium. Pgp, by limiting drug uptake, and CYP3A4, by assisting drug metabolism in the gut and liver, act to limit the bioavailability of cyclosporine and to determine its disposition.⁸³ Cyclosporine is extensively metabolized to more than 20 metabolites. The rate-limiting step in the elimination of cyclosporine is the formation of metabolites, not their clearance. Cyclosporine elimination is not altered in renal failure; however, because of its nephrotoxicity, cyclosporine is avoided in patients with impaired renal function. Liver disease impairs the excretion of cyclosporine metabolites.

Dosage

Effective use of cyclosporine requires that appropriate patients be selected for treatment and monitored carefully (Table 62-3). The starting dosage of cyclosporine is 2.5 mg/

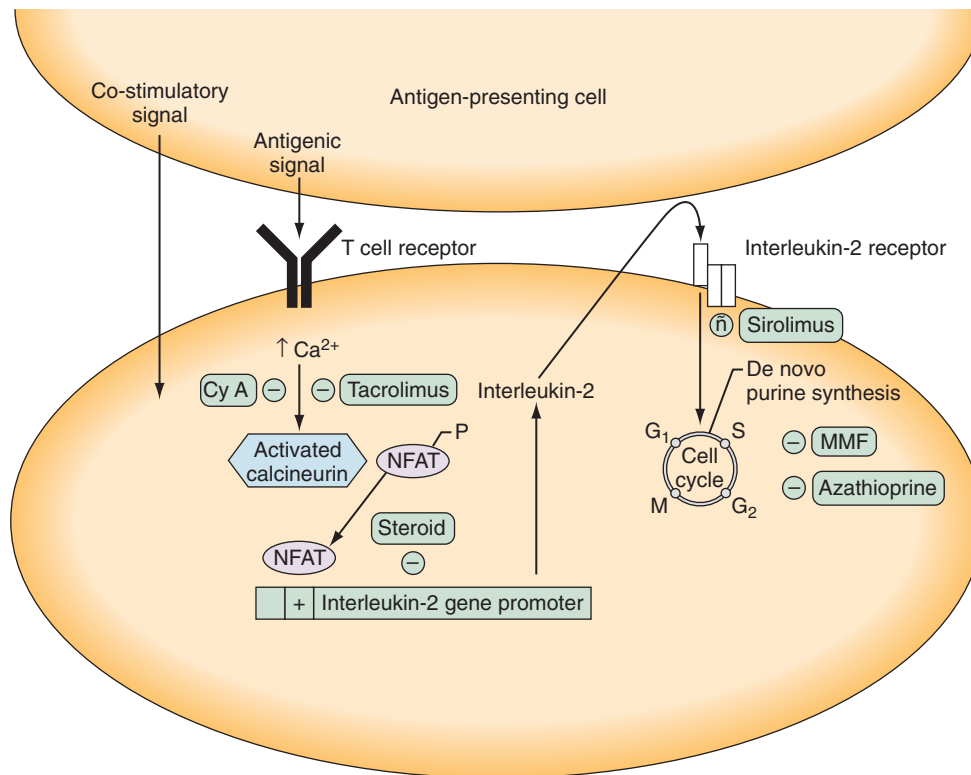

Figure 62-3 Stages of T cell activation. Multiple targets for immunosuppressive agents. Stimulation of the T cell receptor results in calcineurin activation, a process inhibited by cyclosporine (CyA) and tacrolimus. Calcineurin dephosphorylates nuclear factor of activated T cells (NFAT), enabling it to enter the nucleus and bind to interleukin (IL)-2 promoter. Corticosteroids inhibit cytokine gene transcription in lymphocytes and antigen-presenting cells by several mechanisms. Co-stimulatory signals are necessary to optimize T cell IL-2 gene transcription, prevent T cell anergy, and inhibit T cell apoptosis. IL-2 receptor stimulation induces the cell to enter the cell cycle and proliferate. Signal 3 may be blocked by IL-2 receptor antibodies or by sirolimus, which inhibits second messenger signals induced by IL-2 receptor ligation. Following progression into the cell cycle, azathioprine and mycophenolate mofetil (MMF) interrupt DNA replication by inhibiting purine synthesis. (From Denton MD, Magee CC, Sayegh MH: *Immunosuppressive strategies in transplantation*, Lancet 353:1083–1091, 1999.)

kg/day, usually administered in divided doses. In obese patients, dosage is based on the approximate ideal body weight. Clinical response is slow, occurring over 4 to 8 weeks, and may be only maximal after 12 weeks or more of treatment. To improve efficacy, the dosage can be increased by 0.5 mg/kg/day at 4- to 8-week intervals to a maximal

dosage of 4 mg/kg/day of the microemulsion formulation. If there is no clinical response in 4 to 6 months, cyclosporine should be discontinued. In patients who are well controlled, the dosage of cyclosporine can be decreased by 0.5 mg/kg/day at 4- to 8-week intervals to determine the minimal effective dose for the individual patient. In patients receiving the older Sandimmune formulation of cyclosporine who convert to the microemulsion formulation, a 1:1 dose conversion is generally used. Because of the greater and more predictable bioavailability of the microemulsion formulation, however, a greater exposure to cyclosporine is likely. Blood pressure and creatinine should be monitored initially at 2-week intervals after the conversion, and the dose of cyclosporine should be decreased if required.

Table 62-3 Clinical Use of Cyclosporine in Rheumatic Disease

Select appropriate patients
Contraindications:
Current or past malignancy other than basal cell carcinoma, renal impairment, uncontrolled hypertension, hepatic dysfunction
Cautions:
Elderly age, obesity, controlled hypertension, premalignant lesions, drugs that interact with cyclosporine, pregnancy
Obtain ≥ 2 creatinine concentrations before starting cyclosporine, and average these to provide baseline creatinine value
Start low—cyclosporine 2.5 mg/kg/day in divided doses
Stay low—maximum 4 mg/kg/day (microemulsion formulation)
Monitor blood pressure and creatinine initially every 2 wk for 3 mo, then monthly if stable
If serum creatinine increases $>30\%$ above patient's baseline, reduce dosage of cyclosporine by 1 mg/kg/day; recheck serum creatinine in 1–2 wk, and temporarily discontinue cyclosporine if creatinine remains $>30\%$ above baseline
When creatinine level returns to within 15% of baseline, cyclosporine can be restarted at a lower dosage

Clinical Indications

Cyclosporine is effective in the treatment of RA as a single agent and in combination with methotrexate⁸⁴ or hydroxychloroquine, but it is used less commonly now because of the availability of more effective and safer treatment options in early RA.^{85,86} Nevertheless, it remains a useful drug in refractory RA.⁸⁷ Cyclosporine has been shown to increase mean peak plasma methotrexate levels and area under the curve by about 20%⁸⁸; this may contribute to the efficacy of the combination. Data comparing the efficacy and safety of cyclosporine with other disease-modifying antirheumatic

drugs over long periods and in a large number of patients are limited. Cyclosporine is effective for the skin and joint manifestations of psoriasis.⁸⁹ Less data are available regarding the use of cyclosporine in other rheumatic diseases. In uncontrolled, small studies in SLE,⁹⁰ cyclosporine has been reported to improve disease activity; have a glucocorticoid-sparing effect; and improve proteinuria, thrombocytopenia, and leukopenia. The efficacy of cyclosporine as a steroid-sparing drug was confirmed in a randomized clinical trial in patients with severe SLE, but it was not found to be more effective or safer when compared with azathioprine.⁹¹ Cyclosporine has also been reported to be effective in small series of cases in many other autoimmune conditions including pyoderma gangrenosum, Behçet's disease, maintenance therapy of antineutrophil cytoplasmic antibody-associated vasculitis, and macrophage-activation syndrome in juvenile RA.⁹²

Toxicity

Hypertension. Hypertension occurs in approximately 20% of patients with autoimmune disease receiving cyclosporine. The magnitude of increase in blood pressure is usually mild but clinically significant as it increases the risk of stroke, myocardial infarction, heart failure, and other adverse cardiovascular events associated with elevated BP.⁹³ The hypertension should be controlled by reducing the dose of cyclosporine or by antihypertensive drug therapy.⁹⁴

Nephrotoxicity. Virtually all patients who take cyclosporine have a small but measurable decrease in renal function that is reversible after cyclosporine is discontinued. Serum creatinine concentrations have increased approximately 20% in 6- to 12-month clinical trials, but few patients have had to withdraw because of this.⁹⁵ Long-term data regarding renal function in RA patients treated with cyclosporine are limited. In one 12-month study, an increase in serum creatinine of more than 30% occurred in 50% of patients; half of these patients responded to cyclosporine dose reduction, and half did not, requiring discontinuation of the drug.⁹⁴ The small increase in serum creatinine observed in most studies occurs mainly during the first 2 to 3 months of treatment, and then creatinine remains relatively stable over 12 months.^{94,95} Other data suggest, however, that over periods of treatment longer than 1 year, many patients, who over the first year had a stable, acceptable increase in creatinine concentration, subsequently have an increase in creatinine to more than 30% of baseline that is not controlled by cyclosporine dose reduction; such patients have to discontinue treatment.⁹⁶ Preventable risk factors for cyclosporine-induced nephrotoxicity are a high dosage of cyclosporine (>5 mg/kg/day) and an increase in serum creatinine concentration of more than 50% of the baseline value. The risk of cyclosporine nephropathy is low in patients treated according to the clinical guidelines (see Table 62-3).⁹⁷ Renal biopsy specimens in 11 patients with RA who received cyclosporine (average dosage, 3.3 mg/kg/day) for 26 months and had an average increase in serum creatinine of 31% showed no significant cyclosporine-induced renal changes.⁹⁸

Gastrointestinal. Gastrointestinal upset is common but usually mild and transient. A few patients discontinue cyclosporine therapy for this reason, however.

Malignancy. In transplant recipients, cyclosporine use has been associated with an increased risk of skin cancer and lymphoma. In 208 patients with RA treated with cyclosporine for an average of 1.6 years, the incidence of malignancy and mortality was similar to that of RA controls,⁹⁹ but a recent meta-analysis on the risk of immunomodulatory drugs in RA, psoriasis, and psoriatic arthritis did find an increased risk of nonmelanoma skin cancer in patients treated with cyclosporine.¹⁰⁰ Epstein-Barr virus-induced B cell lymphoma, which may be reversible when cyclosporine is discontinued, has been reported in a few patients receiving cyclosporine for a variety of indications.

Others. Other adverse effects that are common but usually of minor significance include hypertrichosis, gingival hyperplasia, tremor, paresthesia, breast tenderness, hyperkalemia, hypomagnesemia, and increase in serum uric acid.⁹⁴ Cyclosporine may result in a clinically insignificant increase in alkaline phosphatase concentrations but does not increase the frequency of abnormal transaminase concentrations in patients also receiving methotrexate.¹⁰¹

Strategies to Minimize Toxicity. Because cyclosporine may increase liver enzymes, potassium, uric acid, and lipid concentrations and decrease magnesium concentrations, it is prudent to measure these before, and occasionally after, initiating therapy. At least two, and preferably more, recent normal blood pressure and serum creatinine determinations should be obtained before starting treatment.

Many patients with RA have low serum creatinine concentrations, and it is important not to overlook significant cyclosporine-induced elevations in serum creatinine, which may remain within the normal laboratory reference range. If a patient has a baseline creatinine level of 0.6 mg/dL that after cyclosporine increases to 0.9 mg/dL (still in the normal range), this represents a 50% increase above baseline and requires dose reduction. Cyclosporine concentrations are not useful predictors of efficacy or toxicity in rheumatic diseases and are not routinely performed. Cyclosporine trough concentrations, measured approximately 12 hours after the last dose, can be useful if there are concerns about compliance or unusual drug disposition in individual patients.

Pregnancy and Lactation

Cyclosporine is an FDA Pregnancy Category C drug. Pregnancy outcomes in transplant recipients receiving cyclosporine-based and noncyclosporine-based regimens are similar. Cyclosporine use in pregnancy is not recommended, however, unless the potential benefit exceeds the potential risk to the fetus. Breastfeeding should be avoided.

Drug Interactions

Cyclosporine and *tacrolimus*, because of the influence of Pgp and CYP3A4 enzyme activity on their disposition, have many clinically important drug interactions (Table 62-4).^{102,103} Many drugs such as *erythromycin*, azole antifungal drugs, and some calcium channel antagonists that inhibit CYP3A4 (inhibiting the metabolism of cyclosporine) also inhibit Pgp. Drug interactions mediated by these dual mechanisms may result in a twofold to fivefold increase in

Table 62-4 Clinically Important Drug Interactions with Cyclosporine*

Increased Cyclosporine Concentrations
Erythromycin, clarithromycin
Azole antifungals: ketoconazole, fluconazole, itraconazole
Calcium channel antagonists: diltiazem, verapamil, amlodipine [†]
Grapefruit juice
Others: amiodarone, danazol, allopurinol, colchicine
Decreased Cyclosporine Concentrations
Inducers of hepatic enzymes: rifampicin, phenytoin, phenobarbitone, nafcillin, St John's wort
Increased Cyclosporine Toxicity
Increased renal toxicity with aminoglycosides, quinolone antibiotics, amphotericin B, (?) nonsteroidal anti-inflammatory drugs, (?) angiotensin-converting enzyme inhibitors
Cyclosporine Increasing Toxicity of Another Drug
Increased risk of myopathy and rhabdomyolysis with lovastatin and other statins
Increased risk of colchicine neuromyopathy and toxicity
Increased digoxin concentrations
Increased risk of hyperkalemia with K ⁺ -sparing diuretics and K ⁺ supplements

*Most interactions with cyclosporine also likely apply to tacrolimus.

[†]There are conflicting data that amlodipine does and does not increase cyclosporine concentrations.

cyclosporine concentrations. Azithromycin, in contrast to erythromycin and clarithromycin, seems unlikely to alter cyclosporine levels. The plasma concentrations and clinical toxicity of several *statin* lipid-lowering agents are increased substantially by cyclosporine, but the pharmacokinetics of fluvastatin and pravastatin, because they are not metabolized primarily by CYP3A4, are altered less by cyclosporine.¹⁰⁴ Nevertheless, the pravastatin area under the concentration curve, a measure of drug exposure, was five times higher in patients also receiving cyclosporine.¹⁰⁵ Of the calcium channel antagonists, *diltiazem*, *nicardipine*, and *verapamil* increase cyclosporine concentrations; *nifedipine* and *amlodipine* have variable effects; and *isradipine* and *nitrendipine* do not generally affect concentrations.¹⁰⁶ It is controversial whether nonsteroidal anti-inflammatory drugs (NSAIDs) increase cyclosporine nephrotoxicity. In many clinical studies, cyclosporine and NSAIDs have been safely co-administered^{184,107}; however, increased cyclosporine-associated nephrotoxicity with NSAIDs has been reported. Currently, many patients starting cyclosporine also take an NSAID. If the creatinine increases, in addition to decreasing the dose of cyclosporine, discontinuing the NSAID may be tried. Grapefruit juice increases plasma concentrations of cyclosporine, so patients should be warned to avoid this.

Tacrolimus (FK506)

Structure

Tacrolimus, previously known as FK506, is a macrolide derived from an actinomycete and is widely used in organ transplantation as an alternative to cyclosporine. Studies in autoimmune disease are less advanced.

Mechanisms of Action

Tacrolimus is about 100 times more potent than cyclosporine and, although structurally different, is also a calcineurin inhibitor. Tacrolimus binds to an intracellular binding protein (FK binding protein), and this drug-immunophilin complex, in association with calcineurin, suppresses transcription of cytokines such as interleukin-2, inhibiting the early steps of T lymphocyte activation (see Figure 62-3).⁷⁹

Pharmacology

Absorption of tacrolimus after oral administration is poor and highly variable (range, 4% to 93%; average, 25%).¹⁰⁸ Tacrolimus is lipophilic, is widely distributed in tissues, and is almost completely metabolized with an elimination half-life of 5 to 16 hours.¹⁰⁹ As with cyclosporine, Pgp and CYP3A4 in liver and gut are important determinants of the metabolism and disposition of tacrolimus. Drugs that inhibit CYP3A4 or Pgp can increase tacrolimus concentrations (see Table 62-4).¹⁰⁸ Impaired hepatic function, but not impaired renal function, increases tacrolimus concentrations.¹⁰⁹

Dosage

Tacrolimus is not routinely used for rheumatologic conditions. Different dosages have been used in clinical studies (see next paragraph).

Clinical Indications

Tacrolimus is effective in animal models of arthritis, but data in humans are limited.^{86,110,111} In a 6-month phase II, randomized, double-blind, placebo-controlled monotherapy study, patients with RA received 2 mg or 3 mg of tacrolimus or placebo daily for 24 weeks. An American College of Rheumatology 20% improvement criteria (ACR20) response was observed in 10.2% of patients receiving placebo and in 18.8% and 26.8% of patients receiving 2 mg and 3 mg of tacrolimus.¹¹¹ A longer-term study of 3 mg of tacrolimus in 896 rheumatoid patients with a median duration of treatment of 359 days yielded ACR20, ACR50, and ACR70 responses of 38.4%, 18.6%, and 9%.¹¹⁰ Topical 1% tacrolimus has been used with moderate success in patients with resistant skin disease secondary to SLE, subacute cutaneous lupus erythematosus, and discoid lupus erythematosus.¹¹² Tacrolimus 0.1 mg/kg/day was effective in seven out of nine patients with diffuse proliferative lupus nephritis refractory to IV cyclophosphamide,¹¹³ but large-scale placebo-controlled trials have not yet been performed in SLE.

Toxicity

The adverse effects of tacrolimus are dose related and include nephrotoxicity, hypertension, hyperkalemia, hyperuricemia, tremor, hyperglycemia, and gastrointestinal intolerance.¹⁰⁸ Among RA patients taking 3 mg of tacrolimus daily for more than 1 year, 59% experienced a side effect, probably or possibly due to the drug including diarrhea

(15%); nausea (10%); tremor (9%); headache (9%); abdominal pain (8%); increased creatinine (7%); hypertension (5%); and pneumonia, pancreatitis, hyperglycemia, and diabetes mellitus (all <1%). A creatinine increase of greater than 30% from baseline to end of study was found in 40%.¹¹⁴

Sirolimus (Rapamycin), Everolimus

Sirolimus, isolated from an actinomycete, and its derivative everolimus have been developed as immunosuppressants for organ transplantation, but the collective experience in rheumatologic conditions is limited. Sirolimus and everolimus, in contrast to cyclosporine and tacrolimus, do not act through calcineurin. They bind to FK binding protein and target proteins variously known as targets of rapamycin (TOR) proteins or FK-rapamycin associated proteins (FRAP), blocking progression of the cell cycle from G₁ to S phase by inhibiting several downstream signal transduction pathways.⁷⁸ Clinical trials have shown efficacy in transplant recipients who also had inflammatory arthritis. A randomized, placebo-controlled, proof-of-concept study with everolimus in 121 RA patients receiving methotrexate (MTX) showed a rapid onset of action with ACR20 response rates that were significantly higher in the everolimus group (36.1%) than in the placebo group (16.7%; $P = 0.022$) after 12 weeks. Adverse events were more common in the everolimus group (mainly gastrointestinal, skin, neurologic).¹¹⁵ Rapamycin was as effective in reducing skin thickening as methotrexate in a small randomized trial in 18 patients with early diffuse cutaneous systemic sclerosis, but 2 patients treated with rapamycin were withdrawn because of severe hypertriglyceridemia.¹¹⁶

Mycophenolate Mofetil

Structure

MMF, a prodrug, is the inactive 2-morpholinoester of mycophenolic acid, which is hydrolyzed to the active mycophenolic acid (MPA), an antibiotic with immunosuppressive effects.¹¹⁷

Mechanism of Action

There are two pathways for the synthesis of guanine nucleotides: the de novo pathway and the salvage pathway. MPA reversibly inhibits inosine monophosphate dehydrogenase, a crucial enzyme for the de novo synthesis of guanosine purines.^{117,118} Lymphocytes, in contrast to many other cells, are critically dependent on the de novo purine synthesis pathway and are a relatively selective target for MPA, accounting for the ability of the drug to inhibit reversibly B cell and T cell proliferation without myelotoxicity.¹¹⁹ MPA results in decreased guanine synthesis and decreased DNA synthesis, decreased lymphocyte proliferation, and decreased antibody production.¹¹⁸⁻¹²⁰ MPA also inhibits proliferation of fibroblasts, endothelial cells, and arterial smooth muscle cells and prevents deposition and contraction of collagen, extracellular matrix proteins, and smooth muscle actin.¹²¹

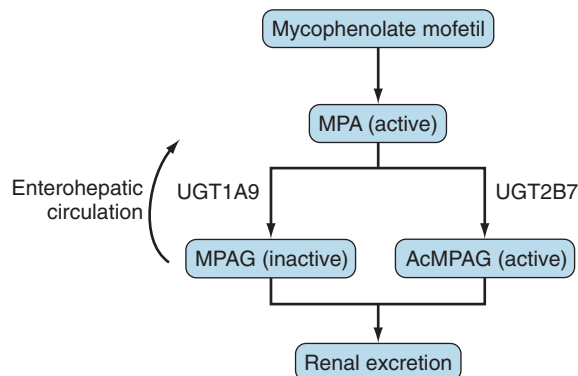

Figure 62-4 Mycophenolate mofetil is converted to mycophenolic acid (MPA) and is subsequently metabolized to its glucuronide (Glu) conjugates, MPAG and AcMPAG, by different isoforms of UDP glucuronidyl transferases (UGT) in the liver. Pathways of enterohepatic circulation of MPA via the glucuronide conjugate metabolites are shown. The majority of MPAG is excreted in urine.

Pharmacology

MMF is rapidly and completely absorbed and de-esterified to the active MPA, which is highly (98%) protein bound. Most MPA (>99%) is found in plasma, with little in cells; most is glucuronidated to the poorly active, stable phenolic glucuronide, which is eliminated in the urine (Figure 62-4).¹²² Minor metabolites, some of which may be active, have also been described. Peak levels of MPA occur 1 to 2 hours after administration, and secondary peaks, thought to be due to enterohepatic circulation, can be seen. The half-life of MPA is 16 hours.¹²² MPA concentrations may vary fivefold to tenfold in individuals receiving the same dose.¹²³ A small amount of this variability may be due to genetic variation in uridine-glucuronosyltransferase enzymes.¹²⁴ Renal disease and liver disease have relatively minor effects on the disposition of the active drug, MPA. Generally dosage adjustments are not required,¹²² but because free MPA concentrations are approximately doubled in patients with severe renal impairment (creatinine clearance < 20 to 30 mL/min),^{125,126} they may be necessary sometimes. The major glucuronide metabolite of MPA accumulates in patients with impaired renal function and may cause increased gastrointestinal side effects. Because MPA is highly protein bound, it is not cleared by hemodialysis.¹²⁷

Toxicity

MMF is generally well tolerated. The most common side effects are gastrointestinal such as diarrhea, nausea, abdominal pain, and vomiting. Occasional infections, leukopenia, lymphocytopenia, and elevated liver enzymes can occur. Of 54 SLE patients treated with MMF over a 3-year period, 16% withdrew because of adverse events, with 73% continuing treatment at 12 months.¹²⁸ In patients with lupus nephritis, diarrhea was more common and serious infections were less common with MMF than with cyclophosphamide.³⁸ Enteric-coated mycophenolate sodium and MMF have similar rates of side effects.¹²⁹ Opportunistic infections including one that was fatal occurred in 3 of 10 patients with idiopathic dermatomyositis who were treated with glucocorticoids and MMF.¹³⁰

Dosage

Effective daily dosages of MMF range from 0.5 to 1.5 g twice a day. In 71 patients with lupus nephritis, the initial dose was 1 g/day with a target of 3 g/day. The mean maximal dose was 2680 mg/day, and 63% of patients tolerated 3 g/day.³⁸

Clinical Indications

In recent years MMF has emerged as a potentially safer alternative to cytostatic agents in the treatment of several rheumatic diseases, notably systemic lupus erythematosus,^{38,131} systemic sclerosis,¹³² vasculitis,¹³³ and inflammatory muscle disease.^{130,134} In a 24-week study in lupus nephritis, mycophenolate was more effective than monthly pulse cyclophosphamide with a failure rate (without complete or partial remission at 24 weeks, plus those who stopped treatment for any reason) of 34 of 71 (47.9%) compared with 48 of 69 in the cyclophosphamide group (69.6%; $P=0.01$).³⁸ In a systematic review of four trials involving 618 patients, MMF was not superior to cyclophosphamide for renal remission and there was no significant difference for adverse events (infections, leukopenia, gastrointestinal symptoms, herpes zoster, end-stage renal disease, and death) except for a lower incidence of alopecia and amenorrhea with the use of MMF compared with cyclophosphamide.¹³⁵ In seven patients with myositis, six had a good clinical and biochemical response to mycophenolate,¹³⁴ an observation that was confirmed in another study in six patients with refractory myositis,¹³⁶ and in three studies in patients with interstitial lung disease associated with dermatomyositis ($n=4$) or other connective tissue diseases including rheumatoid arthritis ($n=10$) and systemic sclerosis ($n=13$), MMF was effective in improving signs and symptoms of lung disease.¹³⁷⁻¹³⁹ MMF may be useful as an alternative immunosuppressant to azathioprine, particularly in patients with gout who require therapy with allopurinol because, in contrast to azathioprine, it does not seem to interact significantly with allopurinol.^{76,119} Mycophenolate 1 g twice daily was not more effective than placebo in two clinical trials involving 443 patients with refractory RA¹⁴⁰ as assessed with ACR20 responses, and a larger mycophenolate-cyclosporine trial was stopped prematurely. Treatment-related adverse events were experienced by 51.6%, 73.1%, and 36.1% of patients receiving MMF, cyclosporine, and placebo, respectively. Hypertension, increased serum creatinine, muscle cramps, hirsutism, and hypertrichosis were more than twice as common with cyclosporine as with MMF. In all three trials the incidence of serious adverse events with MMF was 12.1% (compared with 11.3% and 7.5% for cyclosporine and placebo, respectively). Although mycophenolate is used in psoriasis as an effective alternative to methotrexate, there are only anecdotal reports of its utility in psoriatic arthritis.

Pregnancy and Lactation

MMF is an FDA Pregnancy Category C drug. Mycophenolic acid is associated with miscarriage and congenital malformations when used during pregnancy and should therefore be avoided whenever possible by women trying to conceive. It is transferred into the mother's milk, and extreme caution

should be used in women with childbearing potential and lactating mothers.

Drug Interactions

Because MPA is glucuronidated and not metabolized by CYP oxidation, there are few clinically significant drug interactions. Antacids reduce bioavailability by approximately 15%, and cholestyramine reduces bioavailability by approximately 40%.¹⁴¹ Rifampin treatment reduced MPA concentrations twofold to threefold.¹⁴² Co-administration with azathioprine is not recommended.

THALIDOMIDE

Structure

Thalidomide is a racemic glutamic acid analogue that was introduced in the 1950s as a sedative and antiemetic. The recognition that thalidomide was a potent teratogen resulting in characteristic congenital malformations led to its withdrawal in 1961. The rediscovery of the immunomodulating effects of thalidomide has led to the cautious and closely regulated, but controversial, reintroduction of thalidomide for the treatment of erythema nodosum leprosum. Preliminary studies have explored other potential therapeutic roles.

Mechanism of Action

Multiple mechanisms have been proposed for the immunosuppressive effects of thalidomide, the most plausible being the inhibition of angiogenesis and the inhibition of tumor necrosis factor production.^{143,144}

Pharmacology

Peak concentrations of thalidomide occur 2 to 4 hours after oral administration. The elimination half-life is approximately 5 hours, with elimination being virtually entirely through nonenzymatic hydrolysis.¹⁴⁵ CYP2C19, a polymorphic enzyme, contributes to the formation of an active metabolite, 5-hydroxythalidomide. The pharmacokinetics of thalidomide are poorly characterized, and there is little information regarding drug interactions or use in patients with impaired renal or hepatic function. The sedative effects of other central depressants such as barbiturates are enhanced by thalidomide.

Dosage

Thalidomide is approved by the FDA only for the treatment of erythema nodosum leprosum. Prescription of thalidomide for this indication and its off-label use is closely regulated. In a randomized, controlled trial, thalidomide (100 mg/day and 300 mg/day) for 24 weeks improved the mucocutaneous lesions of Behçet's syndrome. Clinical response was lost rapidly, however, after discontinuation of the drug.¹⁴⁶ Small, largely uncontrolled reports suggest possible benefit in the skin manifestations of lupus, sarcoidosis, RA, Sjögren's syndrome, ankylosing spondylitis, systemic-onset juvenile RA, and pyoderma gangrenosum.¹⁴⁷

Toxicity

The most serious, best-known, and preventable adverse effect of thalidomide is its ability to cause birth defects. In clinical studies, peripheral neuropathy has been the most common serious adverse effect, usually manifesting as painful, symmetric paresthesias. Electrophysiologic changes precede clinical neuropathy, and most studies reporting higher rates of neuropathy have used this diagnostic technique. The neuropathy may become evident only after thalidomide has been discontinued and in most patients (75%) may not resolve completely. Other common adverse effects include sedation, skin rash, limb edema, and constipation. Neutropenia is less common. Ovarian failure¹⁴⁸ and arterial and venous thromboses have been reported.

Strategies to Minimize Toxicity

Strategies to prevent fetal exposure to thalidomide are outlined in the System for Thalidomide Education and Prescribing Safety (STEPS) program developed by the drug's manufacturer, Celgene, and in guidelines developed in the United Kingdom.¹⁴⁹ Registration in the STEPS program is required before thalidomide is used. The program involves mandatory patient registration, education, surveys, and contraception for men and women. Electrophysiologic monitoring for thalidomide-induced neuropathy should be considered if long-term therapy is planned. Thalidomide should be discontinued if peripheral neuropathy occurs. Thalidomide's side effects, its teratogenic effects, and the rapid relapse of autoimmune disease after discontinuation of thalidomide severely limit its therapeutic potential.

CONCLUSION

Immunosuppressive drugs are key therapeutic tools in the management of many rheumatic diseases. They include alkylating agents such as cyclophosphamide and purine analogue cytotoxic drugs such as azathioprine with a long history of clinical use in rheumatology and relatively newer noncytotoxic immunosuppressants such as MMF. In contrast to extracellular, exquisitely targeted therapeutics represented by biologics, our understanding of the in vivo mechanism of action of immunosuppressive drugs is limited. In contrast, their potential efficacy and safety profiles are generally well known and serious toxicities can usually be prevented by careful monitoring of laboratory tests for white blood counts, liver and renal function, and electrolytes. As a general rule combination therapy of the different immunosuppressants discussed earlier should be avoided. The individual response to immunosuppressive therapy can be highly variable, and decisions to continue a chosen immunosuppressant should be revisited on a regular basis weighing the benefits and side effects.

KEY POINTS

Inhibition of a single key cytokine can be effective in autoimmune and inflammatory diseases.

Most patients with rheumatoid arthritis (RA) respond to treatment with tumor necrosis factor (TNF) inhibitors, with significant improvements in signs and symptoms of disease.

Maintaining clinical efficacy with TNF inhibitors usually requires continued therapy, that is, there is no induction of immune tolerance or “cure.” However, there may be a window of opportunity in early RA for inducing long-term remission.

Treatment with TNF inhibitors significantly decreases radiographic damage, improves quality of life, and helps preserve functional status.

Guarded optimism has been expressed regarding the long-term safety of TNF inhibitors.

Combining a TNF inhibitor with methotrexate achieves additive benefits.

TNF inhibitors have also proved highly effective in treating patients with ankylosing spondylitis, psoriatic arthritis, psoriasis, Crohn’s disease, and juvenile idiopathic arthritis.

TNF inhibitors have been ineffective in patients with vasculitis (granulomatosis with polyangiitis [formerly Wegener’s granulomatosis], temporal arteritis).

Although interleukin (IL)-1 inhibition is generally less effective in RA than TNF inhibition, this approach can be highly effective in certain autoinflammatory conditions (e.g., periodic fever syndromes).

IL-6 inhibition is an effective therapy in RA.

Combination biologic therapy appears to increase risk of side effects, such as infection, without additional benefit.

In recent years, discoveries delineating the immunopathophysiologic basis of various rheumatic diseases, combined with biopharmaceutical development, have allowed the introduction of biologic therapeutics. These agents target specific components of the immune response that are dysregulated and are thought to be central to the cause and sustenance of the disease process. In the rheumatoid synovium, for example, substantial evidence has been found of upregulation of key proinflammatory cytokines such as tumor necrosis factor (TNF), interleukin-1 (IL-1), IL-6, and others.^{1,2} Agents targeting these key mediators, in particular TNF, have considerable efficacy in the treatment

Anticytokine Therapies

ZUHRE TUTUNCU • ARTHUR KAVANAUGH

of patients with rheumatoid arthritis (RA) and other systemic inflammatory disorders. The ability of TNF inhibitors not only to improve the signs and symptoms of disease but also to preserve functional status and quality of life and to inhibit disease progression has altered both physicians’ and patients’ expectations regarding antirheumatic treatment. Moreover, their success has driven research into the targeting of other cytokines relevant to the pathogenesis of autoimmune disorders. In this chapter, we focus on therapeutic agents that target TNF, IL-1, and IL-6.

TUMOR NECROSIS FACTOR INHIBITORS

TNF plays a central role in the pathogenesis of RA and other inflammatory disorders. Although it can be produced by numerous cell types, in inflammatory conditions such as RA, TNF is produced largely by activated macrophages. Human TNF is synthesized and expressed as a 26-kD transmembrane protein on the plasma membrane and is cleaved by a specific metalloproteinase (TNF-converting enzyme). After proteolytic cleavage, TNF is converted to a 17-kD soluble protein, which oligomerizes to form the active homotrimer. The actions of TNF are mediated through two structurally distinct receptors: TNF-RI (55 kD; CD120a) and TNF-RII (75 kD; CD120b).³ The two receptors differ in their binding affinities signaling properties, and primary functions.^{3,4} The binding of TNF to its receptor can initiate several signaling pathways. Signaling cascades include the activation of transcription factors (e.g., nuclear factor κ B [NF κ B]), protein kinases (intracellular enzymes that mediate cellular responses to inflammatory stimuli, such as c-JunN-terminal kinase [JNK] and p38 mitogen-activated protein [MAP] kinase), and proteases (enzymes that cleave peptide bonds, such as caspases).

TNF may contribute to the pathogenesis of RA through myriad mechanisms, including induction of other proinflammatory cytokines (e.g., IL-1, IL-6) and chemokines (e.g., IL-8); enhancement of leukocyte migration by increasing endothelial layer permeability and adhesion molecule expression and function; activation of numerous cell types; and induction of the synthesis of acute phase reactants and other proteins, including tissue-degrading enzymes (matrix metalloproteinase enzymes) produced by synoviocytes or chondrocytes. The pivotal role of TNF in mediating such diverse inflammatory activities provided the rationale for targeting this cytokine in systemic inflammatory diseases.⁵ Initially, animal studies proved that inhibition of TNF with monoclonal antibodies or soluble TNF-R constructs ameliorated the signs of inflammation and prevented joint destruction.⁶ Subsequently, studies in humans confirmed the substantial efficacy of these compounds.

Currently, five anti-TNF agents are available for clinical use: infliximab, a chimeric anti-TNF monoclonal antibody; etanercept, a soluble dimeric p75-TNF-R/Fc fusion construct; adalimumab, a human anti-TNF monoclonal antibody; golimumab, a human anti-TNF monoclonal antibody; and certolizumab pegol, a Fab fragment of a recombinant, humanized anti-TNF monoclonal antibody linked to a 40-kD polyethylene glycol (PEG) moiety. For each agent, initial assessment in open-label studies of patients with RA was followed by double-blind, placebo-controlled, randomized clinical trials. Typically, early studies included patients with very active disease that was relatively chronic and refractory. Driven by success in the most difficult populations, studies of all TNF inhibitors have also been performed in patients with early RA. Most studies included patients whose disease remained active despite concurrent use of methotrexate (MTX); some studies assessed the efficacy of a drug as monotherapy. Building on the efficacy achieved in RA, TNF inhibitors have been tested in other inflammatory arthritides, including psoriatic arthritis and ankylosing spondylitis. Moreover, these agents have been studied in other autoimmune conditions, such as Crohn's disease, ulcerative colitis, psoriasis, uveitis, and others.

Although all five available agents are macromolecule TNF inhibitors, differences among them have been noted.⁷ The monoclonal antibodies infliximab, adalimumab, golimumab, and certolizumab pegol are specific for TNF, whereas etanercept binds both TNF and lymphotoxin- α (LT- α ; previously referred to as lymphotoxin). Given intravenously, infliximab has a high peak concentration followed by steady-state elimination, whereas etanercept, adalimumab, golimumab, and certolizumab pegol, because they are given subcutaneously, have "flatter" pharmacokinetic profiles. With the exception of certolizumab pegol, these agents are capable of affecting Fc-mediated functions, such as complement-dependent cytotoxicity and antibody-dependent cell-mediated cytotoxicity, and all bind to both soluble and membrane forms of TNF, although some relative differences in affinity may be noted. Other differences, such as effects on cytokine secretion, have been observed in some *in vitro* studies.⁸ Regarding apoptosis, the data have been somewhat discrepant. In patients with RA, both the anti-TNF monoclonal antibody infliximab and the soluble receptor construct etanercept are capable of inducing apoptosis in synovial macrophages.⁹ However, in patients with Crohn's disease, etanercept was not clinically effective at the doses studied and did not induce apoptosis. In contrast, the anti-TNF monoclonal antibodies infliximab and adalimumab were clinically effective and induced apoptosis in highly activated lymphocytes.¹⁰ However, certolizumab pegol is effective in Crohn's disease and is not able to induce apoptosis. The extent to which these potential differences among TNF inhibitors correlate with any specific aspects of efficacy or toxicity remains to be established.

Infliximab

Structure

Infliximab is a chimeric mouse-human monoclonal antibody composed of constant regions of human immunoglobulin (Ig) G1 κ coupled to the variable regions of a high-affinity neutralizing murine anti-human TNF

antibody. The resulting construct is approximately 70% human (Figure 63-1).

Pharmacokinetics

Clinical pharmacology studies demonstrate that infliximab has a dose-dependent pharmacokinetic profile following infusions of 1 to 20 mg/kg. In combination therapy with MTX (7.5 mg once a week), serum infliximab concentrations tend to be slightly higher than when administered alone.¹¹ Infliximab behaves in a consistent manner across different demographic groups (including pediatric vs. adult patients) and among patients with different diseases of varied severity. The half-life of infliximab is around 8 to 9.5 days at the 3 mg/kg dose, although longer values have been reported for higher doses.¹² The volume distribution of infliximab at steady state (3 to 5 L) is independent of dose, suggesting a predominantly intravascular distribution.^{13,14} Concomitant use of MTX results in an increase in the area under the curve of infliximab of approximately 25% to 30%.

Drug Dose

The typical initial dose of infliximab in RA is 3 mg/kg given as an intravenous (IV) infusion in combination with MTX, followed by doses 2 and 6 weeks after the first infusion, then every 8 weeks thereafter. Some RA patients have received infliximab in combination with disease-modifying antirheumatic drugs (DMARDs) other than MTX or as monotherapy. For patients who have an incomplete response, dosing may be increased up to 10 mg/kg, or the drug may be administered as often as every 4 weeks. In the clinic, increasing the dose of infliximab or decreasing the interval of administration is not an uncommon practice; however, it is not clear to what extent such changes achieve clinical improvements. For patients with psoriatic arthritis and ankylosing spondylitis, the recommended dose is 5 mg/kg, with or without MTX, at 0, 2, and 6 weeks, then every 8 weeks.

Efficacy

Rheumatoid Arthritis. In the earliest controlled trials, the efficacy of single doses of 1, 5, 10, and 20 mg/kg of infliximab was demonstrated; however, disease activity recurred when therapy was discontinued.^{13,15} This, along with the growing safety record, provided the rationale for studies with longer durations of therapy. In a subsequent study, concurrent therapy with MTX, even at a relatively low dose of 7.5 mg/wk, seemed to enhance the clinical response to infliximab and to decrease its immunogenicity.¹¹ Almost all subsequent studies in RA have used such combination therapy.

Multicenter double-blind, placebo-controlled, randomized clinical trials have evaluated the effects of multiple doses of infliximab over longer periods. In the Anti-TNF Trial in Rheumatoid Arthritis with Concomitant Therapy (ATTRACT) trial, the addition of infliximab in patients with long-standing, refractory, active disease was significantly superior to treatment with MTX alone. The results were promising: Substantial improvement in signs and symptoms of disease was noted soon after treatment and was sustained though 54 weeks of follow-up.^{12,16} In addition to

TNF INHIBITORS

Figure 63-1 Structures of infliximab, etanercept, adalimumab, golimumab, and certolizumab pegol. CDR, complementarity-determining region; CH1, complement fixation; FC, fragment crystallizable; FDA, U.S. Food and Drug Administration; PEG, polyethylene glycol; TNF, tumor necrosis factor; VH, variable heavy; VL, variable light.

achieving substantial efficacy, the use of infliximab was associated with significant improvement in functional status and quality of life.¹⁶ Perhaps most remarkably, patients receiving infliximab had a dramatic reduction in the progression of joint damage as assessed by radiographic change scores. The median change in the Sharp score at 1 year for infliximab-treated patients was 0.0 unit (mean change, +0.55; baseline score, 50.5), indicating no significant progression. The median change in score for patients on MTX alone was +4.0 units (mean change, +7.0; baseline score, 55.5); this amount of progression is roughly what would have been predicted given the disease severity.^{14,16}

Following the success achieved in patients with longstanding RA, this therapy was tested in patients with early RA (<3 years' duration). In the ASPIRE trial, significant improvement in disease activity was noted in patients treated with infliximab plus MTX in comparison with MTX alone, at 54 weeks. In addition, although a significant increase in radiographic destruction was observed in patients treated only with MTX, a reduction in disease progression was observed in the infliximab plus MTX groups.¹⁷ A detailed subanalysis of data from the ATTRACT study demonstrated that a significant radiographic benefit was achieved with infliximab plus MTX treatment even among patients who experienced no improvement in signs and symptoms of disease. This suggests that there may be an uncoupling among various outcomes, and that treatment with TNF inhibitors might lead to disease-modifying activity even in the absence of a clinical response.¹⁸

In a safety-based study, a group of patients with active RA and disease more typical of clinic populations (i.e., patients with comorbidities were allowed to enroll) were

treated with 3 or 10 mg/kg of infliximab for 46 weeks, resulting in comparable efficacy to that found in earlier trials.¹⁹ However, an increase in serious infectious events was reported in the 10 mg/kg group.

Psoriatic Arthritis (PsA). In the Infliximab Multinational Psoriatic Arthritis Controlled Trial 1 (IMPACT 1), patients with or without background DMARDs were randomized to receive infliximab or placebo for 16 weeks; thereafter, all patients received infliximab until week 50. The response to infliximab therapy defined by American College of Rheumatology 20% response criteria (ACR20) and PsA response criteria was evident as early as week 2, and improvement continued through week 50. Significant improvements were also seen in skin psoriasis and in dactylitis and enthesitis assessments.²⁰

In the phase III (IMPACT 2) trial, clinical improvement was seen very early in the infliximab-treated groups, and the response was maintained with continued treatment through the end of the study. Significant dermatologic improvement, defined by changes in the Psoriasis Area and Severity Index (PASI), was also reported in the infliximab group.^{21,22} In the same group of patients, infliximab inhibited radiographic progression as early as 24 weeks. Thus, the change in the van der Heijde–Sharp score was -0.70 ± 2.53 versus 0.82 ± 2.62 at week 24 for infliximab- and placebo-treated patients, respectively. At week 54, these scores continued to improve: -0.94 versus 0.53 for infliximab and placebo crossover patients, respectively.²³

In the same study, the effect of infliximab on health-related quality of life was assessed. The mean percentage improvement from baseline in the health assessment questionnaire (HAQ) was 48.6% in the infliximab group,

compared with a worsening of 18.4% in the placebo group at week 14. Overall, 58.6% of the infliximab group and 19.4% of the placebo group achieved a clinically meaningful improvement in HAQ at week 14.²⁴

Ankylosing Spondylitis. The efficacy and safety of infliximab have been assessed in several multicenter clinical trials.²⁴⁻²⁷ In the initial double-blind, placebo-controlled, randomized part of one early study, disease activity measured by the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), functional ability measured by the Bath Ankylosing Spondylitis Functional Index (BASFI), and mobility of the spine measured by the Bath Ankylosing Spondylitis Metrology Index (BASMI) significantly improved with 5 mg/kg infliximab given at weeks 0, 2, 6, and 12 compared with placebo.²⁵ Of patients who continued to receive infliximab every 6 weeks until week 102, a significantly higher percentage achieved 50% or greater improvement in the BASDAI.^{26,27} At week 102, 25% of the completers were in partial remission according to the Assessment in Ankylosing Spondylitis (ASAS) criteria. The clinical efficacy and the partial remission achieved in a substantial minority of patients were maintained through 3 years of treatment. In addition, the incidence of enthesitis and anterior uveitis significantly decreased during the third year of treatment in comparison with baseline.²⁸ This group was also analyzed for the clinical response and the time to relapse after discontinuation of anti-TNF therapy. Of note, after infliximab was stopped, all patients experienced a return of disease activity, with a mean time to relapse of 17.5 weeks. Retreatment with infliximab was safe and resulted in clinical improvement in all patients to a state similar to that achieved previously.²⁹

In another trial, most of the patients who received 5 mg/kg infliximab at 0, 2, 6, and 12 weeks reached ASAS 20% response criteria (ASAS20) at week 24, in comparison with 19% of the placebo group. Efficacy was noted as early as 2 weeks after the beginning of therapy and was maintained throughout the 24-week observation period. At week 24, 22.4% of patients in the infliximab group achieved ASAS partial remission, in comparison with 1.3% in the placebo group. In addition, patients receiving infliximab showed significant improvement in BASDAI, BASFI, and BASMI.³⁰

To assess the effects of treatment on inflammation and structural damage, magnetic resonance images of the lumbar spine and sacroiliac joints were assessed. Spinal inflammation and clinical disease activity improved significantly from week 0 to week 30 in patients treated with infliximab plus MTX, in comparison with MTX alone.³¹ In one study, 2 years of continuous infliximab therapy resulted in persistent improvement in spinal inflammation determined by both T1-weighted gadolinium-enhanced and short tau inversion recovery magnetic resonance imaging (MRI) sequences in all ankylosing spondylitis (AS) patients ($n = 20$).³² Of note, disease activity parameters did not directly correlate with MRI results.

Etanercept

Structure

Etanercept is formed by the linkage of two soluble p75 TNF-R extracellular domains to the Fc portion of human

IgG1 (see Figure 63-1). The resultant molecule binds both TNF and LT- α with high affinity and specificity.³³ The TNF-R domains in etanercept bind to two of the three receptor binding sites on the TNF trimer, thus blocking the ability of TNF to interact with cell-bound TNF-R—a prerequisite for signal transduction³² (see Figure 63-1).

Pharmacokinetics

When administered subcutaneously, etanercept is absorbed slowly, reaching a mean peak concentration approximately 50 hours after a single 25-mg dose. The Ig structure affords a half-life of 3 to 4.8 days. The volume of distribution suggests predominantly intravascular distribution.³⁴ The route of clearance from the circulation is unclear, although it is presumed to be mediated through Fc binding by the reticuloendothelial system. Different from what has been seen with anti-TNF monoclonal antibodies, concomitant use of MTX does not appear to alter the pK of etanercept.

Drug Dose

Etanercept is administered by subcutaneous injection in doses of 25 mg twice weekly or 50 mg once weekly in RA, PsA, and ankylosing spondylitis. Etanercept is approved for use as monotherapy or in combination with MTX. In skin psoriasis, a higher dose (50 mg twice weekly) is commonly used for the first 12 weeks of therapy. As is true of all available TNF inhibitors, in the clinic, etanercept has been used in combination with DMARDs other than MTX, for example, leflunomide, sulfasalazine, and others.

Efficacy

Rheumatoid Arthritis. Initial studies demonstrated the efficacy and tolerability of etanercept in both early and refractory disease and also established the optimal dose as 25 mg twice weekly.³⁵⁻⁴⁵ In addition to achieving substantial efficacy, as measured by ACR20 clinical response criteria, the use of etanercept has been associated with significant improvement in functional status and quality of life. In one double-blind, placebo-controlled, randomized clinical trial, patients with active and long-standing RA who were refractory to DMARD therapy were treated with etanercept (10 or 25 mg twice weekly) for 6 months. Etanercept rapidly reduced disease activity.³⁷ In another trial, the addition of etanercept in patients with active disease, despite concurrent MTX, was significantly superior to treatment with MTX alone.³⁸ At 6 months, disease activity was significantly reduced in the combination therapy group versus those who received only MTX. In the open-label extension part of this study, patients were able to sustain the improvement, and most were able to decrease their use of MTX, corticosteroid, or both.

Following the success achieved in patients with refractory disease, the role of TNF inhibitors in the treatment of early disease was demonstrated in a large clinical trial in which two doses of etanercept (10 or 25 mg twice weekly) were compared with an accelerated dosing of MTX in MTX-naïve RA patients with disease of less than 3 years' duration.^{39,40} Clinical efficacy was achieved more quickly with the standard dose of etanercept than with MTX or

lower-dose etanercept. Moreover, radiographic assessments at 0, 6, 12, and 24 months showed that the rate of radiographic progression was significantly reduced with etanercept compared with MTX.

In long-term, open-label follow-up studies of patients from the clinical trials, responses to etanercept therapy have been sustained over a number of years, with some patients having received more than a decade of treatment.⁴¹ Etanercept has also proved efficacious in patients with juvenile arthritis.⁴² In a study known as TEMPO, etanercept plus MTX was shown to be superior to MTX or etanercept alone in patients with relatively early disease. Similarly, improvement in disability based on HAQ was greater with combination therapy. The etanercept plus MTX group showed significantly less radiographic progression than did either group receiving monotherapy, and radiographic progression was significantly less in the etanercept group compared with the MTX group. Because no pK interaction occurs between etanercept and MTX, this study conclusively shows an additive effect on various important outcome results with the combination of MTX and a TNF inhibitor.⁴³

Different dosing of etanercept has been assessed in clinical trials. In RA patients, 50 mg etanercept once weekly resulted in similar efficacy to 25 mg twice weekly.⁴⁴ Of note, etanercept monotherapy at a dose of 50 mg twice weekly did not result in increased efficacy in RA patients compared with 25 mg twice weekly.⁴⁵

Psoriatic Arthritis. In the initial double-blind, placebo-controlled clinical trial, substantial improvements were observed in PsA response criteria, ACR20 response criteria, and PASI dermatologic scores in the etanercept-treated patients. The median PASI improvement was 46% in the etanercept group versus 9% in the placebo group.⁴⁶

Subsequently, 205 patients with PsA were randomized to treatment with placebo or 25 mg etanercept twice weekly. At week 12, 59% of etanercept-treated patients met the ACR20 criteria, compared with 15% of placebo patients. During the open-label extension through week 48, patients continuing with etanercept treatment maintained or improved their clinical responses, while those in the placebo group showed similar improvements once they began receiving etanercept. The primary radiographic end point was the annualized rate of change in the modified total Sharp score. Radiographic disease progression was inhibited in the etanercept group (−0.03 unit) compared with worsening (+1.00 unit) in the placebo group.⁴⁷

Ankylosing Spondylitis. Similarly positive results were observed with etanercept therapy in patients with ankylosing spondylitis. In a double-blind, placebo-controlled, randomized clinical trial, significant improvement in clinical response (defined by ASAS20) was demonstrated in etanercept-treated patients throughout the 24-week study.⁴⁸ Sustained clinical response was maintained in the open-label extension of this study throughout 96 weeks of treatment.⁴⁹ Health-related quality of life assessments also significantly improved with etanercept.⁵⁰ The extent of clinical response was similar in subsequent clinical trials. Improvement measured by ASAS20 was noted as early as 2 weeks after etanercept was started, and the response was maintained throughout the trial.⁵¹ In a subsequent multicenter trial, significant improvements in BASDAI, BASFI, and BASMI scores were achieved initially in the

etanercept-treated group, and later in all patients after the placebo group received etanercept as well. Relapses occurred at a mean of 6 weeks after cessation of etanercept.⁵² Re-administration of etanercept led to similar results in the same group of patients. Most patients were able to completely discontinue nonsteroidal anti-inflammatory drugs (NSAIDs).⁵³

In one clinical trial, magnetic resonance images of the lower thoracic and lumbar spine of 40 patients were evaluated. Spinal inflammation regressed by 54% in the etanercept group but worsened by 13% in the placebo group after 12 weeks of therapy. After switching to etanercept, placebo patients experienced a similar improvement in spinal inflammation.⁵⁴ Finally, it was demonstrated that continuous treatment with etanercept for 24 weeks reduced active spinal changes by 69% as measured by different MRI sequences.⁵⁵

Adalimumab

Structure

Adalimumab is a human anti-TNF IgG1κ monoclonal antibody generated through repertoire cloning. Adalimumab neutralizes the biologic activity of TNF by binding with high affinity to the soluble and transmembrane forms of TNF and inhibiting the binding of TNF with its receptors (see Figure 63-1).

Pharmacokinetics

The peak serum adalimumab concentration and the area under the curve increase linearly with doses in the range of 0.5 to 10 mg/kg. Adalimumab appears to have a low clearance and distributes mainly in the vascular compartment. Its elimination half-life is comparable with that of native IgG1 (10 to 13.6 days). Concomitant use of MTX results in an approximate increase in the area under the curve of adalimumab of 25% to 30%.

Drug Dose

The recommended dosing for adalimumab in RA, PsA, and ankylosing spondylitis is 40 mg subcutaneously every other week. In patients who do not achieve an optimal response, it is possible to increase the dosing frequency to weekly. Adalimumab is approved for use as monotherapy or in combination with MTX. In the clinic, it has been used in combination with a number of DMARDs other than MTX.

Efficacy

Rheumatoid Arthritis. In a phase II trial, adalimumab (20, 40, or 80 mg) via weekly subcutaneous injection for 12 months demonstrated efficacy in comparison with placebo.⁵⁶ In a subsequent trial, adalimumab provided significant, rapid, and sustained improvement in disease activity over 24 weeks compared with MTX alone in patients with active RA despite long-term MTX therapy.⁵⁷ In a study known as ARMADA, combined treatment with adalimumab and MTX demonstrated sustained improvement in the signs and symptoms of RA as assessed by American College of

Rheumatology (ACR) criteria, as well as notable improvement in functional status as assessed by HAQ scores.⁵⁸ In a phase III multicenter trial, 619 patients with active RA and inadequate response to MTX were randomized to receive adalimumab 40 mg every other week, adalimumab 20 mg weekly, or placebo.⁵⁹ Both adalimumab regimens were significantly more effective at reducing signs and symptoms and improving physical function in comparison with placebo. In addition, joint damage was assessed radiographically using Sharp scores; patients treated with adalimumab showed significantly smaller changes, and significantly fewer adalimumab-treated patients had new erosions and overall progression of damage compared with those taking placebo. A study evaluating health-related quality of life in two clinical trials demonstrated that adalimumab plus MTX provides statistically significant improvements.⁶⁰ Long-term follow-up of patients receiving open-label treatment after several controlled trials has demonstrated sustained improvement and good tolerability over several years.⁶¹

Following the efficacy noted in patients with refractory RA, adalimumab was assessed in patients with early disease. In a study known as PREMIER, adalimumab plus MTX was superior to adalimumab or MTX monotherapy in MTX-naïve patients with early RA (active disease <3 years' duration) at 1 year. Significantly less radiographic progression was observed among patients in the combination group at both 1 year and 2 years in comparison with the monotherapy groups, although progression was less with adalimumab monotherapy than with MTX monotherapy.⁶² Because this study was the first to include all three possible treatment arms (TNF inhibitor, MTX, and TNF inhibitor plus MTX), it definitively established that combination therapy with MTX and TNF inhibitor achieves the best outcomes in patients with early RA. Although TNF inhibitor monotherapy was superior to MTX alone in terms of radiographic progression, clinical efficacy was comparable; however, each of these was substantially less effective than the combination.

Psoriatic Arthritis. Adalimumab given as 40-mg subcutaneous injections every other week has also been studied in patients with PsA. In a large placebo-controlled trial with 313 patients, 50% of patients were on background MTX. A significantly higher percentage of patients from the adalimumab-treated group reached ACR20, -50, and -70 response criteria compared with those receiving placebo.⁶³ Moreover, the rate of radiographic damage progression was significantly attenuated with adalimumab. As was true in studies of the other TNF inhibitors in PsA MTX was permitted but not required for enrollment in the study. With this design, there seemed to be no difference in efficacy or toxicity between the combination of MTX plus adalimumab and adalimumab monotherapy. In addition to improvements in various articular manifestations, dramatic improvements were noted in skin psoriasis with adalimumab treatment.

Ankylosing Spondylitis. In the adalimumab trial evaluating long-term efficacy and safety in ankylosing spondylitis (known as the ATLAS trial), a total of 315 patients received either 40 mg adalimumab or placebo every other week for 24 weeks. The number of subjects who met ASAS partial remission criteria was significantly higher in the adalimumab group at weeks 12 and 24 in comparison with

the placebo group. Subjects meeting ASAS 5/6 criteria (20% improvement in five of six domains, without 20% worsening in the sixth domain) at weeks 12 and 24 were also significantly more in the adalimumab-treated group.⁶⁴ Significant improvement in health-related quality of life was reported in this group of patients.⁶⁵ The efficacy of these drugs was demonstrated not only by improved clinical indices but also by spinal inflammation as assessed by MRI.

Golimumab

Structure

Golimumab is a human IgG1κ monoclonal antibody specific for human TNF. Golimumab was created using genetically engineered mice immunized with human TNF, resulting in an antibody with human-derived antibody variable and constant regions (see Figure 63-1).

Pharmacokinetics

Following subcutaneous administration of golimumab to healthy subjects and patients with RA, the median time to reach time to peak concentration (T_{max}) ranged from 2 to 6 days. Golimumab exhibited dose-proportional pharmacokinetics in patients with active RA over the dose range of 0.1 to 10.0 mg/kg following a single intravenous dose. The volume distribution for golimumab indicates that golimumab is distributed primarily in the circulatory system with limited extravascular distribution. Median terminal half-life values were estimated to be approximately 2 weeks in healthy subjects and patients with RA, PsA, or AS. When golimumab 50 mg was administered subcutaneously to patients with RA, PsA, or AS every 4 weeks, serum concentrations appeared to reach steady state by week 12. With concomitant use of MTX, treatment with golimumab every 4 weeks resulted in a mean steady-state trough serum concentration of approximately 0.4 to 0.8 µg/mL in patients with RA, PsA, or AS. Concomitant MTX usage resulted in higher mean steady-state trough concentrations of golimumab in patients with RA, PsA, or AS (52%, 36%, and 21% respectively), compared with those treated with golimumab alone.⁶⁶

Drug Dose

Golimumab is administered by subcutaneous injection, 50 mg once a month, in patients with RA, PsA, and AS.

Efficacy

Rheumatoid Arthritis. Results of a phase II study of golimumab in 172 patients with active RA despite MTX therapy demonstrated the efficacy of golimumab given every 4 weeks by subcutaneous injection in combination with MTX. The clinical effect was evident as early as 2 weeks after the first dose and was sustained to 1 year.⁶⁷ The efficacy and safety of golimumab were evaluated in three multicenter, double-blind, placebo-controlled trials. Golimumab was administered subcutaneously at doses of 50 mg or 100 mg every 4 weeks. In the GO-FORWARD study, patients with active RA despite a stable dose of MTX who

had not been previously treated with a biologic TNF inhibitor were randomized to receive golimumab 50 mg + MTX, golimumab 100 mg + MTX, or golimumab 100 mg monotherapy every 4 weeks. All golimumab regimens were significantly more effective at reducing signs and symptoms and in improving physical function.⁶⁸ Patients who had less than 20% improvement in swollen and tender joint count entered early escape at week 16. The proportion of patients who achieved ACR20 and reached a low disease activity score at week 52 was significantly greater in the golimumab group. Patients who were treated with 100 mg of tocilizumab appeared to have increased risk of serious adverse events and serious infections.⁶⁹

Patients who were previously treated with one or more doses of TNF inhibitor without a serious adverse reaction were enrolled in the GO-AFTER study. Greater efficacy measured by ACR20 and Disease Activity Score (DAS) 28 was observed in patients who received golimumab 50 mg plus MTX at week 14 compared with patients who received MTX alone. Improvements in HAQ scores were also markedly higher for patients receiving golimumab plus MTX in comparison with MTX alone.⁷⁰

Patients with active RA who were MTX-naïve and had not been previously treated with TNF inhibitor were randomized to be treated with MTX alone, golimumab 50 mg plus MTX, golimumab 100 mg plus MTX, or golimumab 100 mg alone in the GO-BEFORE study. Golimumab plus MTX led to significant improvement in ACR responses (ACR50, 40%) at 24 weeks in MTX-naïve patients compared with patients who received MTX alone (ACR50, 29%).⁷¹

An MRI substudy of the GO-BEFORE and GO-FORWARD trials demonstrated that patients who received golimumab plus MTX had improvements in inflammation (synovitis and osteitis) exceeding those observed with MTX only as early as week 12 and continuing through week 24. Significant improvements in erosions were also observed in the GO-BEFORE trial.^{72,73}

Psoriatic Arthritis. The GO-REVEAL study evaluated the efficacy and safety of golimumab in PsA patients. Four hundred five patients with active PsA despite NSAID or DMARD therapy who had not been previously treated with TNF inhibitor were randomized to receive golimumab 50 mg or 100 mg with or without MTX every 4 weeks. Fifty-one percent of patients who received golimumab reached ACR20 response at week 14 in comparison with 9% of patients who received only MTX. Significant improvements in enthesitis and HAQ scores were seen in patients treated with golimumab, in addition to significant improvements in the psoriasis skin lesions evaluated with PASI responses.⁷⁴ Long-term radiologic outcome was assessed using the van der Heijde-Sharp (vdH-S) method modified for PsA. Golimumab 50 mg and 100 mg given to patients with active PsA showed no to minimal evidence of radiographic disease progression through week 104.⁷⁵

Ankylosing Spondylitis. The efficacy of golimumab in AS was evaluated in the GO-RAISE study. Three-hundred fifty-six patients with active AS according to modified New York criteria were randomized to receive placebo, golimumab 50 mg, or golimumab 100 mg every 4 weeks. Patients were allowed to be on stable doses of sulfasalazine, hydroxychloroquine, low-dose corticosteroids, or NSAIDs during

the trial. The use of other DMARDs was prohibited. At weeks 14 and 24, golimumab 50 mg once a month demonstrated significant ASAS20 and ASAS40 responses (56% and 44%, respectively) versus placebo (23% and 15%, respectively).⁷⁶

Certolizumab Pegol

Structure

Certolizumab pegol is a Fab fragment of a recombinant, humanized anti-TNF monoclonal antibody that has been fused to a 40-kD polyethylene glycol (PEG) moiety. The Fab fragment is composed of a light chain with 214 amino acids and a heavy chain with 229 amino acids. Given this structure, certolizumab is not able to effect Fc-mediated activities that can be mediated by full monoclonal antibody and constructs containing Fc pieces such as complement-dependent or antibody-dependent cell-mediated toxicity or apoptosis.

Pharmacokinetics

Single intravenous and subcutaneous doses of certolizumab pegol have predictable dose-related plasma concentrations with a linear relationship between the dose administered and the peak concentration (C_{max}). A mean C_{max} of approximately 43 to 49 µg/mL occurred at week 5 in patients with RA at the recommended dose regimen. Following subcutaneous administration, peak plasma concentrations of certolizumab pegol were attained between 54 and 171 hours post injection. PEGylation delays the metabolism and elimination of these entities from the circulation by a variety of mechanisms, including renal clearance, proteolysis, and immunogenicity. The terminal elimination phase half-life was approximately 14 days for all doses tested.

Drug Dose

The recommended dose of certolizumab pegol is 400 mg initially and at weeks 2 and 4, followed by 200 mg every other week. For maintenance dosing, certolizumab pegol 400 mg every 4 weeks can be considered. A 400-mg dose is given as two subcutaneous injections of 200 mg at separate sites in the thigh or abdomen.

Efficacy

Intravenous ascending-dose monotherapy with certolizumab pegol was shown to effectively control the signs and symptoms of RA in a phase II trial.⁷⁷ The efficacy and safety of certolizumab pegol were assessed in multiple randomized, placebo-controlled, double-blind studies. RAPID-I and RAPID-II studies included patients with active RA despite MTX. Both were 52 week studies that evaluated the lyophilized (RAPID-I) or the liquid (RAPID-II) preparation of certolizumab with endpoints of progression of structural damage (change from baseline in modified Sharp score) and signs and symptoms of RA measured by ACR20, -50, and -70. Patients were randomized to receive loading doses of 400 mg of certolizumab pegol or placebo at weeks 0, 2, and 4 followed by 200 mg of certolizumab pegol, 400 mg

certolizumab pegol, or placebo every other week in combination with MTX. Certolizumab pegol-treated groups showed rapid and sustained improvement in clinical disease activity starting from week 1 and sustained through week 52. Mean radiologic progression was significantly reduced in the certolizumab-treated groups versus MTX alone.^{78,79} Rapid and sustained improvements in health-related quality of life, fatigue, home and workplace productivity, and social activities were also reported in patients treated with certolizumab pegol in RAPID-I and -II trials.^{80,81} Sustainability of improvements in RA signs and symptoms and inhibition of joint damage progression, as well as tolerability of certolizumab pegol + MTX, were evaluated in the RAPID-II open-label extension study. Results at 3 years showed that 400 mg every other week dosing did not significantly increase the efficacy outcome; certolizumab pegol was generally well tolerated; and clinical and radiologic improvements were sustained over this period of time.⁸² In a broader group of RA patients with inadequate response to more than one DMARD, including prior TNF inhibitor exposure, addition of certolizumab pegol to the regimen resulted in rapid clinical response measured with ACR20 response rates and DAS28 scores, and improved function measured with HAQ scores.⁸³

Mechanism of Action of TNF Inhibitors

Several potential mechanisms of action may explain the efficacy of TNF inhibitors in RA and other conditions (Table 63-1). Although some support has been put forth for these varied mechanisms, the exact relationship between any particular mechanism and specific aspects of clinical efficacy remains to be delineated. Downregulation of local and systemic proinflammatory cytokine production and reduction of lymphocyte activation and migration into the joint may be the most relevant mechanisms; for example, serum levels of IL-6 and IL-1 are significantly reduced after

administration of anti-TNF monoclonal antibody.^{84,85} The reduction in TNF and the consequent reduction in IL-1 would be expected to reduce the synthesis of matrix metalloproteinase (MMP) and the production of other degradative enzymes. Serial studies have shown that there is in fact a marked reduction in pro-MMP-3 and pro-MMP-1 after anti-TNF therapy.⁸⁶⁻⁸⁸ As noted, anti-TNF therapy is also associated with a reduction of lymphocyte migration into the joints of patients with RA. Using radiolabeled granulocytes, it has been demonstrated that anti-TNF monoclonal antibody significantly reduces cell movement into the affected joints.⁸⁹ In addition, post-treatment synovial biopsies show reduced cellular infiltrates, with fewer T cells and macrophages present.⁹⁰ These effects are thought to be secondary to a reduction in the expression of endothelial adhesion molecules in the synovial tissue. Treatment with anti-TNF monoclonal antibody results in a dose-dependent decrease in soluble forms of intercellular adhesion molecule-1 (ICAM-1) and E-selectin (CD62E).⁸⁹ Changes in soluble E-selectin, soluble ICAM-1, and circulating lymphocytes with anti-TNF therapy correlate with clinical outcomes. Vascular endothelial growth factor (VEGF) is a potent endothelial cell-specific angiogenic factor. It is produced in the synovium and is an important regulator of neovascularization in the pannus. After anti-TNF therapy, VEGF serum levels are reduced in patients with RA. This decrease correlates significantly with the clinical benefit observed in these patients.⁹¹ Because angiogenesis is a prominent feature of rheumatoid synovium, the relationship between inflammation and angiogenesis has been investigated. Computerized image analysis of endothelium for multiple markers of endothelium (e.g., von Willebrand factor, CD31) and neovasculature ($\alpha v\beta 3$) has shown reduced vascularity after anti-TNF therapy. A number of other potential mechanisms of action have been suggested to be operative for TNF inhibitors (see Table 63-1), although debate on these aspects is ongoing.

Table 63-1 Potential Mechanisms of Action of Tumor Necrosis Factor Inhibitors

Decrease Production of Other Inflammatory Mediators
Cytokines (e.g., IL-1, IL-6, GM-CSF)
Chemokines (e.g., IL-8)
Degradative enzymes (e.g., MMPs)
Other mediators (e.g., C-reactive protein)
Alter Vascular Function; Leukocyte Traffic and Activation
Decreased adhesion molecule expression and function
Angiogenesis inhibition
Modulate the Function of Immunocompetent Cells
T Cells
Normalize activation threshold for CD3-T cell receptor signaling
Alter Th1/Th2 phenotype, cytokine secretion
Increase regulatory T cell number and function
Induce apoptosis (?)
Monocytes and Macrophages
Modulate HLA-DR expression
Possibly increase apoptosis (?)

GM-CSF, granulocyte-macrophage colony-stimulating factor; HLA-DR, human leukocyte antigen DR; IL, interleukin; MMPs, matrix metalloproteinases; Th, T helper.

Other Considerations

Treatment in Other Autoimmune Conditions

The role of TNF inhibitors in the treatment of Crohn's disease, juvenile idiopathic arthritis, and psoriasis has been clearly defined. Based on promising results in various immune conditions, these agents have been used in a variety of other disorders, including idiopathic and spondyloarthritis-related anterior uveitis, sarcoidosis, Sjögren's syndrome, Behçet's syndrome, inflammatory myopathies, and various types of vasculitis. Although a number of case reports or small, uncontrolled clinical trials have reported on these conditions, there is a paucity of conclusive data from controlled trials. Perhaps the most notable clinical response has been observed in the treatment of anterior uveitis, especially with anti-TNF monoclonal antibody constructs.⁹² On occasion, promising results in uncontrolled trials have been disproved in controlled trials. This was observed in a placebo-controlled trial of etanercept given in addition to standard therapy for remission induction and maintenance in patients with granulomatosis with polyangiitis (formerly Wegener's granulomatosis). Despite promising anecdotal evidence, the

addition of the TNF inhibitor not only failed to achieve any clinical improvement but also resulted in greater risk of solid malignancies beyond that observed with cyclophosphamide alone.⁹³

Despite evidence that anti-TNF agents can result in the development of certain autoantibodies and even lupus-like syndromes, the safety and efficacy of anti-TNF agents have been assessed in a small group of patients with systemic lupus erythematosus (SLE). Patients with joint involvement experienced remission of arthritis, and a significant reduction in the level of proteinuria occurred with infliximab. In this small study, TNF inhibitor therapy did not lead to adverse events suggestive of an increase in SLE activity; however, as might have been expected, autoantibodies to double-stranded DNA and cardiolipin did increase.⁹⁴

Cardiovascular Risk and Lipid Profile

Cardiovascular morbidity and mortality appear to be increased in autoimmune conditions. This may be related both to increased prevalence of traditional risk factors for cardiovascular disease and to uncontrolled systemic inflammation, which appears to predispose independently to accelerated progression of atherosclerosis. Treatment with TNF inhibitors appears to be associated with overall improvement in cardiovascular disease risk, related to beneficial effects on lipid parameters and to control of systemic inflammation.^{95,96} Long-term investigations are needed to define the possible beneficial effects of TNF inhibitors on overall and cardiovascular survival in patients with autoimmune disease.^{95,96}

Monitoring

All patients must be evaluated for active and inactive (latent) tuberculosis infection before initiation of therapy. Appropriate screening tests (e.g., tuberculin skin test, ex vivo testing for tuberculosis, chest x-ray) should be performed on all patients. Use of TNF inhibitor therapy may increase the risk of reactivation of hepatitis B virus (HBV) among those who are chronic carriers of HBV. Therefore evaluating patients for HBV before starting TNF inhibitor therapy is recommended. No other specific laboratory monitoring is currently required by regulatory agencies during therapy with TNF inhibitors. Nevertheless, because of the rare occurrence of myelosuppression and concern about the risk of infection, clinicians typically assess the complete blood count (CBC) intermittently during therapy. Assiduous monitoring of patients for any sign or symptom of infection, demyelinating disease, and malignancy is requisite during treatment with all TNF inhibitors. Repeat testing at regular intervals (e.g., annually) for exposure to tuberculosis has been recommended by some regulatory authorities.

Pregnancy and Breastfeeding

Developmental toxicity studies in rats, rabbits, and mice have not revealed any maternal toxicity, embryo toxicity, or teratogenicity associated with TNF inhibition. Minimal human pregnancy information has been published for these

medications, and most data consist of isolated case reports, retrospective surveys, and uncontrolled studies. As the number of patients treated with TNF inhibitors increases, a growing number of pregnancies will be reported among them.⁹⁷ Outcome data based on anecdotal observations of small numbers of pregnant women treated with infliximab, etanercept, and adalimumab reveal that the relative rates of live births, miscarriages, and therapeutic terminations were comparable with rates in a national cohort of age-matched healthy women. TNF inhibitors are classified as U.S. Food and Drug Administration (FDA) Pregnancy Category B (animal reproduction studies have failed to demonstrate a risk to the fetus, and no adequate and well-controlled studies have been performed in pregnant women). The use of anti-TNF agents in pregnancy is recommended only if such treatment is clearly needed. If TNF inhibitors are used during pregnancy, it must be noted that transfer to the fetus is possible, and monitoring might be considered on that basis. Because it is not currently known whether TNF blockers are excreted in human milk, or whether they are absorbed systemically after ingestion, it is recommended that TNF blockers not be used by nursing mothers.

Vaccinations

It is preferred to have all recommended vaccinations brought up to date before initiating treatment with TNF inhibitors. Because data on the response to live vaccinations or the secondary transmission of infection by live vaccinations in patients receiving TNF inhibitors are insufficient, concurrent administration of live vaccines with TNF inhibitors is not recommended.

Toxicity

In clinical trials, etanercept, infliximab, adalimumab, golimumab, and certolizumab pegol have generally been well tolerated.* Longer-term follow-up of patients initially enrolled in clinical trials has provided additional safety data for these agents. However, TNF plays a key role not only in the pathogenesis of autoimmune disease but also in normal immune homeostasis. Therefore, a number of safety considerations, including the potential risk of infection and malignancy, are germane to the optimal clinical use of these agents.⁹⁸

Additional information concerning adverse effects associated with these agents has been obtained through pharmacovigilance. Adverse events related to the use of TNF inhibitors can be grouped into those that are agent-related and those that are target-related (Table 63-2).⁹⁹ Injection site and infusion reactions and immunogenicity and their sequelae vary, depending on the particular agent. A potentially increased predisposition to infection, development of malignancy, and induction of autoimmune disorders and an association with demyelinating disorders, myelosuppression, and worse outcomes with congestive heart failure might be considered target-related adverse events. Thus, any clinically effective TNF inhibitor might be expected to be

*References 12, 16, 35-37, 56, 71, 80, 81.

Table 63-2 Adverse Effects Potentially Associated with Tumor Necrosis Factor Inhibitors

Target-related
Infections (including serious infections)
Opportunistic infections (e.g., tuberculosis)
Malignancies (skin cancer, lymphoma [?])
Demyelinating conditions
Hematologic abnormalities
Congestive heart failure
Autoantibodies (antinuclear antibody, anti-double-stranded DNA)
Hepatotoxicity
Dermatologic reactions
Lupus-like syndromes
Agent-related
Administration reactions
Immunogenicity

associated with such adverse events, although the relative risk among different agents may vary, depending on dose and other factors.

Infusion and Injection Site Reactions. Infliximab has been associated with infusion reactions, the most common of which are headache (20%) and nausea (15%). These are rarely severe, are usually transient, and typically can be controlled by slowing the rate of infusion or by treating with acetaminophen or antihistamines.^{12,16} With etanercept, adalimumab, golimumab, and certolizumab pegol, cutaneous reactions at injection sites represent the most frequent administration-related side effect; however, they rarely lead to discontinuation of therapy.^{30,58,70,81} Injection site reactions typically consist of erythematous or urticarial lesions. Although they can arise at sites of previous injections, these reactions seem to be limited to the skin and are not associated with other or systemic features of immediate hypersensitivity. Reactions typically occur close to treatment initiation and abate over time, even with continued dosing.

Antigenicity. As is true for any therapeutic agent (especially large protein molecules, some of which contain foreign sequences), antibodies to anti-TNF agents can develop. Although the clinical relevance of these antibodies is presently unclear, they can diminish the half-life of the therapeutic agent and consequently decrease its efficacy. Approximately 3% of etanercept-treated patients develop antibodies to the drug. In an early study, it was noted that antibodies to infliximab developed in 53%, 21%, and 7% of patients who were receiving 10, 3, and 1 mg/kg infliximab, respectively.¹² RA trials of infliximab with or without concomitant MTX treatment revealed that immunogenicity was decreased by concomitant MTX, perhaps owing in part to the increase in the half-life of infliximab associated with MTX use.¹² A multicenter trial of infliximab therapy in Crohn's disease demonstrated that induction of these anti-infliximab antibodies might contribute to hypersensitivity reactions in some patients. Antibodies to adalimumab, golimumab, and certolizumab pegol developed in about 4% to 12% of patients; this rate was reduced to 1% with concurrent MTX treatment.^{70-76,78-81,99} Although it is believed that there is a trend toward higher clearance of TNF inhibitors in the presence of antibodies to the construct, routine testing for antibodies to TNF

inhibitors is not widely available, nor is it currently recommended.

Infection. Given that TNF is a key mediator of inflammation, a major concern surrounding the use of TNF inhibitors is their potential to increase the risk of infection. Although inhibition of TNF in animals does not appear to increase their risk for infection with most pathogens, it does interfere with the ability to mount an inflammatory response against intracellular organisms. In experimental models, TNF blockade impaired resistance to infection with mycobacteria,^{100,101} *Pneumocystis carinii*,¹⁰² fungi,¹⁰³ *Listeria monocytogenes*,¹⁰⁴ and *Legionella*.¹⁰⁵ In patients with RA, infection with these types of opportunistic organisms has been observed.^{96,97} However, confounding the attribution of infection to any therapeutic agent is the fact that infections occur more frequently and are important contributors to the accelerated morbidity of RA patients compared with the normal population.^{106,107} It is difficult to determine how much of this susceptibility relates to the disease itself and how much is caused by the effects of immunomodulatory drugs (e.g., steroids, disease-modifying antirheumatic drugs [DMARDs]). The subset of RA patients with great susceptibility to infection (i.e., those with severe, active disease) is also the subset most commonly enrolled in trials of TNF inhibitors; this is the group of patients for whom these agents have the greatest clinical utility.

In RA trials with TNF inhibitors, a number of infections have occurred. In general, the most frequent infections have been those that occur most commonly among all persons, such as upper and lower respiratory tract infections and urinary tract infections. In most studies, a slightly greater propensity to develop infection was seen in patients receiving TNF inhibitors; however, this trend is common in most studies of effective therapies for RA. The incidence of serious infection, defined as infection requiring hospitalization or treatment with parenteral antibiotics, among RA patients treated with TNF inhibitors was similar to that of the control groups in individual studies; it also approximated the incidence noted among RA patients before the anti-TNF era.^{108,109} In certain subgroups, such as patients with early RA, the overall incidence of infection was less than in patients with more long-standing disease, and infections and serious infections were comparable among TNF inhibitor-treated patients and controls.

It is worth noting, however, that several characteristics of clinical trials may affect investigators' ability to extrapolate their safety data to the clinic. In general, patients enrolled in clinical trials tend to be healthier and therefore less likely to develop adverse effects such as infection, compared with the general population of RA patients in the clinic. Therefore, postmarketing data provide an important complement to safety data obtained from clinical trials. Also, clinical trials are powered to assess efficacy and therefore may not include sufficient numbers of patients to ascertain real but small differences in uncommon side effects. A systematic analysis that combined the results from nine clinical trials of TNF inhibitors has been performed.¹⁰⁹ This analysis found an increased risk of serious infection among patients receiving TNF inhibitors compared with controls (3.6% vs. 1.7%); however, it should be noted that a nonstandard definition of serious infection was used, and no attempt was made to control for the time of exposure,

which was nearly always longer for patients receiving TNF inhibitors. In this same analysis, a nonsignificant trend toward a greater incidence of serious infection was observed with higher doses of TNF inhibitor. In one of the only clinical trials that had a primary outcome of safety, use of a high-dose TNF inhibitor was also associated with a greater incidence of serious infection compared with a lower dose; the lower dose was no different from placebo in this regard.¹⁹

In postmarketing surveillance data, also known as pharmacovigilance, serious infections have certainly been observed among patients receiving TNF inhibitors.⁹⁸ The relative impact of potentially confounding factors such as comorbidities and concomitant medications on the rate of serious infection remains incompletely defined. This important question has also been addressed by using registries of RA patients.^{110,111} In a German registry, rates of infection and serious infection among 858 RA patients receiving treatment with TNF inhibitors were compared with those among 601 patients receiving only DMARDs.¹⁰⁸ The relative risk for infection (3.3 to 4.1) as well as serious infection (2.7 to 2.8) was significantly higher among patients receiving TNF inhibitors. However, these patients also had more severe and more active RA, thereby placing them at greater risk of infection. When the investigators used propensity scoring methods to control for severity of disease as a confounder, the relative risks were reduced. The risk of infection decreased to 2.3 to 3.0, and that for serious infection became a nonsignificant trend of 2.1. In data from a British registry, 7644 RA patients treated with TNF inhibitors were compared with 1354 RA patients on DMARDs alone.¹⁰⁹ In this analysis, the crude rate of serious infection was higher among TNF inhibitor-treated patients (1.28; 95% confidence interval [CI], 0.94 to 1.76), although this did not reach statistical significance. Further, when the rates were adjusted for age, sex, severity of RA, use of corticosteroids, and comorbidity, no differences between the groups were noted (relative risk [RR], 1.03; 95% CI, 0.68 to 1.57).

In summary, although treatment with TNF inhibitors can result in increased risk of infection and serious infection, other factors such as the severity of RA, the use of other medications such as corticosteroids, and the presence of comorbidities are important contributors to these outcomes. Clinicians must monitor patients closely for signs and symptoms of infection, and it is worth noting that TNF inhibitor therapy itself can mask the initial signs and symptoms of infection.

Opportunistic infections, particularly disseminated *Mycobacterium tuberculosis*, are of concern with the use of TNF inhibitors. Of note, more patients treated with TNF inhibitors have extrapulmonary and disseminated tuberculosis (TB), highlighting the specific role of TNF in controlling this infection.¹¹² Rates of TB associated with the use of TNF antagonists are higher in geographic regions where TB is more prevalent in the general population.¹¹³ Most cases of TB observed in the early years after the introduction of TNF inhibitors arose within the first few months after initiation of therapy and were probably related to the reactivation of latent TB. Very few cases of TB were observed during clinical trials of the TNF inhibitors, highlighting the important role of pharmacovigilance in identifying safety signals with new therapies. For etanercept, no cases of TB occurred

in clinical trials, but 38 cases of etanercept-associated TB were reported worldwide among an estimated 150,000 patients exposed through December 2002. For infliximab, 441 cases of TB were reported among approximately 500,000 initially exposed patients; only 6 cases of infliximab-related TB were reported from clinical trials. Ninety-seven percent of infliximab-related cases occurred within 7 months of treatment initiation, with a median time of onset of 12 weeks. The incidence of TB in clinical trials with adalimumab was greater in earlier clinical trials; this was related to lack of screening, the locations of the studies, and the higher doses used in early trials. The incidence dropped to 1% after adalimumab was reduced to its current dose, and after screening for latent TB infection was instituted before therapy (21 cases in 2400 patients).^{114,115} The incidence of TB was even lower in golimumab and certolizumab pegol trials. The incidence of TB was 0.23 in golimumab clinical trials, and most cases occurred in countries with a high incidence rate of TB.⁷⁰⁻⁷⁶ In studies with certolizumab pegol, 36 cases of TB occurred among 2367 exposed patients; these cases also occurred in countries with endemic rates of TB. This highlights the benefit of screening for and treating latent TB among patients being considered for TNF inhibitor therapy.⁷⁸⁻⁸¹ However, because treated patients may acquire new cases of TB, and because cases of latent TB may be missed owing to false-negative screening tests, constant vigilance for TB is required during therapy with TNF inhibitors.

The impact of screening for latent TB in patients receiving anti-TNF agents has been assessed in a Spanish registry; the rate of development of active TB among RA patients treated with anti-TNF agents dropped by 83% with use of the recommended guideline.¹¹⁶ Current U.S. guidelines recommend purified protein derivative (PPD) skin testing and/or ex vivo testing for tuberculosis, as well as a chest radiograph, before anti-TNF therapy is initiated. If the PPD test is positive without evidence of active infection, treatment for latent TB with isoniazid is recommended. The recommended duration of therapy is 9 months. Recommendations concerning the timing of TNF inhibitor therapy and isoniazid prophylaxis for latent TB vary; however, concomitant initiation appears feasible.¹⁹ During anti-TB treatment, alanine aminotransferase (ALT) monitoring is recommended, especially for those who chronically consume alcohol and/or who take potentially hepatotoxic drugs. Treatment should be adjusted according to local guidelines.¹¹⁷

Malignancy. Anti-TNF drugs can theoretically affect the host defense against malignancy. To date, the occurrence of malignancies in clinical trials and long-term follow-up of RA patients from clinical trials do not appear to exceed the rate that would be expected in this population. The overall rate of most malignancies in patients with RA is the same as in the normal population. However, risks of lymphoma and lung cancer appear to be increased in patients with RA. Although the actual reason is not known, the severity and duration of the disease and the use of immunomodulatory agents such as MTX seem to play a role in the increased risk of lymphoma in RA patients.¹¹⁸ Postmarketing analysis of the association between anti-TNF agents and lymphoma is inconclusive. In one population-based analysis, standardized incidence ratios of lymphoma

among patients receiving anti-TNF therapies were somewhat higher than those among RA controls; however, this analysis did not adjust for baseline differences between patients.¹¹⁸

In a more recent analysis, in which age, sex, and disease duration adjustments were made, no increased risk of lymphoma was identified among RA patients treated with anti-TNF agents compared with those treated with other therapies.¹¹⁹ The systematic review of clinical trials of anti-TNF monoclonal antibodies demonstrated an increased risk of malignancies, including lymphomas and skin cancers, with treatment, although the longer time of exposure to TNF inhibitors was not accounted for.¹⁰⁸ As anti-TNF agents are being used more frequently in children, a possible increased risk of malignancies in children with autoimmune disorders, particularly in those receiving TNF inhibitors, has been pointed out by the Adverse Event Reporting System of the FDA. Forty-eight reports of malignancy were identified: 31 following infliximab use, 15 following etanercept use, and 2 following adalimumab use. Half of the malignancies were lymphomas, and most cases involved concomitant use of other immunosuppressants.¹²⁰ Given these uncertainties, caution is indicated when the use of anti-TNF agents is considered for patients with a history of malignancy or for those at high risk of malignancy for other reasons. Longer-term follow-up of larger numbers of patients will provide clinicians with a better idea of the safety of these agents in this regard.

Autoimmune Disorders. Approximately 10% to 15% of patients treated with any TNF inhibitor develop antibodies to double-stranded DNA.^{98,121} However, few patients (0.2% to 0.4%) develop symptoms consistent with drug-induced lupus. The mechanism and the significance of the development of antibodies are uncertain, although this adverse effect seems relatively specific for TNF inhibitors and is not noted with other biologic agents. Of note, patients with TNF inhibitor–related lupus generally do not develop life-threatening lupus involvement (e.g., nephritis, central nervous system lupus) and rarely develop the diversity of other autoantibodies characteristic of idiopathic SLE (e.g., anti-Sm/RNP, anti-Ro/La, anti-Scl70). A few patients have reportedly developed anticardiolipin antibodies, but they are mostly asymptomatic. Among those few patients who developed lupus-like symptoms while on TNF inhibition therapy, improvement has been seen upon discontinuation of therapy. Although the rare occurrence of autoimmune disorders has not dissuaded most clinicians from using TNF inhibitors in patients with RA, some remain cautious about using these drugs in patients with a history of SLE.

Demyelinating Syndromes. Several cases of multiple sclerosis (MS) or peripheral demyelinating disease have been reported with anti-TNF therapy in patients with RA, PsA, and Crohn's disease.¹²² In addition, two studies of TNF inhibitors in MS patients showed worsening of MS-related symptoms and exacerbations in the treated group.^{123,124} Although some evidence suggests that the incidence of MS may be increased in patients with RA, the association between anti-TNF therapy and MS remains unclear. The risk of developing a demyelinating disease is very small; however, many clinicians withhold anti-TNF therapy in

patients with a history of demyelinating diseases and in those showing signs and symptoms of such disease during anti-TNF therapy.

Congestive Heart Failure. Data suggest that TNF may play a role in the pathogenesis of congestive heart failure (CHF), and inhibition of TNF was highly effective in animal models of ischemic cardiomyopathy. However, in trials of TNF inhibitors in patients with stable but severe (class III or IV) CHF, no clinical benefit was observed, and in some treatment arms, higher incidences of mortality and hospitalization for worsening of CHF were reported. Thus, TNF inhibition has been largely abandoned as a therapeutic approach in patients with CHF. In patients with RA, treatment with TNF inhibitors does not appear to result in an increased incidence of CHF.¹²⁵ In fact, TNF inhibitor therapy may actually improve mortality associated with heart disease and overall mortality in RA patients.

INTERLEUKIN-1

Members of the IL-1 family include IL-1 α , IL-1 β , and the naturally occurring IL-1 receptor antagonist (IL-1Ra). Specific cellular proteases process IL-1 α and IL-1 β to their 17-kD mature forms. Pro-IL-1 α precursor is active intracellularly. However, pro-IL-1 β is not active before cleavage with IL-1 β -converting enzyme. After cleavage, it is secreted and is fully functional. IL-1Ra is a naturally occurring antagonist protein with amino acid sequence homology to IL-1 α and IL-1 β . Multiple forms of this protein exist. One is secreted and functions as a competitive inhibitor of IL-1 α and IL-1 β , binding to the same counterreceptor but transducing no signal. The IL-1 polypeptides bind to two cell surface receptors: type I (IL-1RI) and type II (IL-1RII). IL-1RI is found on most cell types, whereas IL-1RII occurs mainly on the surface of neutrophils, monocytes, B cells, and bone marrow progenitor cells. When IL-1 binds to IL-1RI, the signal transduction is mediated through the association of a second receptor unit, IL-1R accessory protein. The three members of the IL-1 family bind to IL-1RI with similar affinities. Binding of IL-1 to IL-1RII does not lead to signal transduction. IL-1RII acts like a decoy receptor and a competitive inhibitor. Soluble forms of IL-1RII inhibit IL-1 activity by competing with IL-1RI for IL-1 binding. IL-18 is another member of the IL-1 family of inflammatory cytokines. It is now recognized as an important regulator of innate and acquired immune responses. IL-18 is expressed at sites of chronic inflammation, in autoimmune diseases, in a variety of cancers, and in the context of numerous infectious diseases. IL-18 likely plays a role in RA, and strategies to block IL-18 activity are under way in clinical trials.¹²⁶

As with TNF, IL-1 is one of the key mediators of the inflammatory response. Studies in animal models of arthritis have demonstrated the therapeutic potential of IL-1 blockade. IL-1 β gene knockout mice show markedly reduced levels of inflammation following immunization with type II collagen. The use of genetically modified mice has helped to confirm the physiologic significance of IL-1Ra: Deletion of this gene in mice results in the spontaneous development of arthritis.

Anakinra

Structure and Mechanism of Action

Anakinra is a recombinant, nonglycosylated homolog of IL-1R that differs from native human IL-1R by the addition of a single methionine residue at its amino terminus. Anakinra blocks the activity of IL-1 by competitively inhibiting IL-1 binding to the IL-1RI receptor¹²⁶ (Figure 63-2). Levels of the naturally occurring IL-1R, which are elevated in the synovium and synovial fluid from RA patients, appear to be insufficient for the excess amount of locally produced IL-1.

Pharmacokinetics

In subjects with RA, maximum plasma concentrations of anakinra occur 3 to 7 hours after the subcutaneous administration of clinically relevant doses (1 to 2 mg/kg). The terminal half-life ranges from 4 to 6 hours. In RA patients, no unexpected accumulation of anakinra is observed after daily subcutaneous doses for up to 24 weeks. Estimated anakinra clearance increases with increasing creatinine clearance and body weight.

Drug Dose

The recommended dose of anakinra for the treatment of patients with moderately to severely active RA is 100 mg/day administered by subcutaneous injection. Anakinra can be used alone or in combination with MTX. Because of the potential for increased risk of infection, it is not recommended for use in conjunction with TNF inhibitors.

Efficacy

Rheumatoid Arthritis. Preliminary clinical studies indicated that anakinra could be safely administered by subcutaneous injection.¹²⁷ The efficacy of anakinra in the treatment of active RA was confirmed in a 24-week, phase II, placebo-controlled study in which 472 patients received daily subcutaneous injections of placebo or one of the three different doses of anakinra (30, 75, or 150 mg).¹²⁸ Improvements were observed in all individual clinical parameters,

including swollen and tender joint counts, pain score, duration of early morning stiffness, and patient and physician assessment of disease activity. More patients on the higher dose of anakinra achieved improvement in ACR20 criteria compared with the placebo group. However, the overall magnitude of the reduction in clinical symptoms and signs (20% to 30%) was relatively modest compared with that seen with TNF-blocking agents (60% to 70%). Patients were allowed to go on to a non-placebo-controlled extension study with three different doses of anakinra after completing the 24-week double-blind study. On completion of the extension study, 55% of patients who had previously received placebo achieved an ACR20 response. Of the patients who continued receiving the same dose of anakinra, 49% maintained an ACR20 response at 48 weeks. Analysis of hand radiographs by two different methods after 24 weeks of treatment showed a statistically significant decrease in the rate of progressive joint damage compared with placebo.¹²⁹ Improvements in functional status and quality of life were also observed.¹³⁰

Anakinra is a competitive inhibitor of IL-1 that must be continuously present in great excess to be effective, and it must be administered daily. It was hypothesized that the relatively modest clinical results seen with anakinra in RA patients (compared with those achieved by TNF inhibitors) might be related to the agent rather than to the target. Two lines of evidence appear to refute this hypothesis: the efficacy of anakinra in other inflammatory diseases, and the comparable clinical efficacy of other IL-1 inhibitors in RA.

Other Inflammatory Diseases. Autoinflammatory diseases are a group of conditions that include familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (also known as chronic infantile neurologic, cutaneous, articular [CINCA] syndrome). These conditions, which share some clinical features, are associated with various mutations in the *NALP3/CIAS1/PYPAF1* gene, which encodes the protein cryopyrin. Cryopyrin is a key component of the inflammasome; thus, the autoinflammatory syndromes may be related to abnormalities in IL-1 regulation. This was proved by the remarkable responses to anakinra reported in these syndromes.^{131,132} In addition,

Figure 63-2 A and B, Anakinra. Structure and mechanism of action: Anakinra is a recombinant, nonglycosylated homologue of the interleukin-1 receptor (IL-1R). It blocks the activity of IL-1 by competitively inhibiting IL-1 binding to the IL-1RI receptor.

significant and rapid responses have been achieved when anakinra was used to treat patients with adult-onset Still's disease. Improvement in various hematologic, biochemical, and other markers suggests that IL-1 plays a key role in this disease as well.¹³³

Rilonacept

Rilonacept, previously known as IL-1 Trap, is a fusion protein consisting of the human IL-1 receptor extracellular domains and the Fc portion of human IgG1. It incorporates in a single molecule the extracellular domains of *both* receptor components required for IL-1 signaling: IL-1RI and the IL-1R accessory protein (Figure 63-3). Rilonacept has a very high binding affinity for IL-1 (dissociation constant ≈ 1 pM), and it is specific for IL-1 β and IL-1 α . Based on early studies, the subcutaneous administration of rilonacept in subjects with RA provided evidence of its clinical and biologic activity. However, a double-blind, placebo-controlled clinical trial in patients with moderate to severe RA who were randomized to receive weekly injections of placebo or several doses of rilonacept for 12 weeks showed only modest efficacy.¹³⁴ Rilonacept is approved for cryopyrin-associated periodic syndrome (CAPS) disorders: FCAS and MWS.¹³⁵ This agent's effect on controlling gout attacks is currently being investigated in various clinical trials.

Canakinumab

Canakinumab is a human monoclonal antibody that selectively targets interleukin-1 β . It has no cross-reactivity with other members of the interleukin-1 family, including interleukin-1 α . It is approved for the treatment of CAPS.¹³⁶ Clinical trials with canakinumab in patients with gout are still ongoing.

Other Considerations

Toxicity

Anakinra is generally well tolerated. Injection site reactions are the most frequently reported adverse event. In a randomized clinical trial, injection site reactions were reported in 25% of patients given placebo and in 50%, 73%, and 81% of patients given anakinra in doses of 30, 75, and 150 mg/day, respectively.¹⁰⁷ These reactions were generally mild and transient. Infections were uncommon and occurred at a similar rate in the placebo and treatment groups. Infections that required antibiotic therapy occurred in 12% of the placebo-treated group and in 15% to 17% of the treatment group. These infections consisted primarily of bacterial events such as cellulitis and pneumonia. The incidence of pulmonary infection appeared to be higher among patients with underlying asthma. In placebo-controlled studies, up to 8% of patients receiving anakinra showed a reduction in the neutrophil count, compared with 2% of placebo patients. Other adverse events reported were headache, nausea, diarrhea, sinusitis, influenza-like syndrome, and abdominal pain. Malignancy rate and incidences were similar to those expected for the populations studied. Long-term follow-up of patients on anakinra has proved the overall tolerability of therapy over several years.¹³⁷

In animal studies, the combination of TNF inhibition and IL-1 inhibition achieved synergistic efficacy in arthritis models. However, when this approach was tested in RA patients, the combination did not achieve any additional clinical benefit but did result in greater toxicity—specifically, an increased incidence of infection and serious infection.¹³⁸ Therefore, the combination of biologic therapies targeting TNF and IL-1 is currently not recommended.

Figure 63-3 Rilonacept. Structure: Rilonacept is a fusion protein consisting of the human interleukin (IL)-1 receptor extracellular domains and the Fc portion of human IgG1.

Monitoring

Patients should be closely monitored for signs and symptoms of infection. Administration of anakinra must be discontinued if a patient develops serious infection. Neutrophil counts should be assessed before anakinra treatment is initiated, as well as monthly during anakinra therapy for 3 months, and then every 4 months for up to 1 year.

Pregnancy and Breastfeeding

Reproductive studies have been performed only on rats and rabbits, and they have not revealed any evidence of harm to the fetus. However, no well-controlled studies have been conducted in pregnant women. Therefore, anakinra should be used during pregnancy only if it is clearly needed. It is not known whether anakinra is secreted in human milk, so it should be discontinued in nursing mothers.

INTERLEUKIN-6

Research into the molecular mechanism of IL-6 and other members of the IL-6 cytokine family suggests a potentially critical role in inflammatory and immune responses. IL-6 is a small polypeptide characterized by a four- α -helix bundle structure that is stabilized by intramolecular disulfide bridges. IL-6 is secreted by various cell types, including monocytes, T and B lymphocytes, and fibroblasts. It is detectable at elevated levels in the serum and synovial tissue in inflammatory arthritides, including RA and PsA.¹³⁹ IL-6 exerts its activity by binding its receptor component, IL-6R, which exists in soluble and membrane-bound forms, and the accessory protein, glycoprotein 130 (gp130). The IL-6R is constitutively expressed on several cell types, including lymphocytes and hepatocytes. However, soluble forms of IL-6R can productively interact with the 130 kD signal transducing component gp130, which is expressed on a wide range of cell types (Figure 63-4). IL-6 has multiple effects on various aspects of the immune system to initiate inflammation. IL-6 stimulates the production of T helper (Th)17 cells. These pathogenic cells secrete IL-17 and are

involved in the induction of autoimmune injury.¹⁴⁰ IL-6 also plays a role in B cell activation and differentiation. Effects of IL-6 on osteoclast differentiation and activation, including receptor activator of NF κ B (RANK) ligand-dependent mechanisms, have been clearly demonstrated.¹⁴¹ Recruitment of neutrophils to the inflammatory sites and stimulation of VEGF synergistically with TNF and IL-1 β contribute to pannus formation.¹⁴² Levels of IL-6 are directly proportionate with levels of CRP and disease severity. IL-6 knockout mice are resistant to CIA and show reduced levels of serum TNF.¹⁴³ All these functions make IL-6 blockade an attractive biologic target therapy for the treatment of RA and other autoimmune diseases.

Tocilizumab

Structure and Mechanism of Action

Previously referred to as *myeloma receptor antibody* (MRA), tocilizumab is a humanized IgG1 monoclonal antibody that binds with high affinity to soluble and membrane-bound forms of the 80-kD component of the IL-6R. Tocilizumab is a recombinant humanized antihuman interleukin-6 (IL-6) receptor monoclonal antibody of the immunoglobulin IgG1 κ (gamma 1, kappa) subclass with a typical H₂L₂ polypeptide structure. Each light chain and heavy chain consists of 214 and 448 amino acids, respectively. The four polypeptide chains are linked intramolecularly and intermolecularly by disulfide bonds. Tocilizumab has a molecular weight of approximately 148 kD. Treatment with this monoclonal antibody effectively inhibits IL-6-mediated interactions on cells constitutively expressing the IL-6R. In addition, as noted, soluble forms of the IL-6R can productively interact with the 130-kD signal-transducing component gp130, which is expressed on a wide range of cell types; thus, treatment with tocilizumab effectively inhibits a broad array of IL-6-driven processes.

Pharmacokinetics

Tocilizumab has a nonlinear pharmacokinetic profile.¹⁴⁴ The maximum concentration increases in approximate

Figure 63-4 Interleukin (IL)-6. Mechanism of action: IL-6 binds first to the membrane-bound IL-6 receptor (mIL-6R). The IL-6/mIL-6R complex then associates with the signal-transducing membrane protein, gp130.

proportion to increases in dosage, whereas the area under the concentration-time curve increases disproportionately. As the dosage increases, clearance and the apparent elimination rate constant decrease, and terminal half-life and mean residence times are prolonged. Methotrexate therapy, alcohol consumption, age, and race have not been found to affect the pharmacokinetics of tocilizumab. Tocilizumab binds to soluble IL-6R in a dose-dependent manner and saturates the receptor at approximately 0.1 $\mu\text{g/mL}$. Tocilizumab also competitively inhibits IL-6 binding to soluble IL-6R; complete inhibition is seen at approximately 4 $\mu\text{g/mL}$.¹⁴⁵

After intravenous dosing, tocilizumab undergoes biphasic elimination from the circulation. In patients with RA, the central volume of distribution was 3.5 L, and the peripheral volume of distribution was 2.9 L, resulting in a volume distribution at steady state of 6.4 L.

Drug Dose

Indications for the use of tocilizumab vary across the globe. In the United States, initial approval for tocilizumab in late 2009 was for it to be used alone or concomitant with methotrexate or other DMARDs in treating adult patients with rheumatoid arthritis in whom one or more anti-TNF agents had failed. Recommended starting dose is 4 mg/kg followed by an increase to 8 mg/kg based on clinical response. In other countries, it is recommended to start therapy at 8 mg/kg, with the possibility of reducing to 4 mg/kg, for example, in the case of tolerability concerns. It is administered once every 4 weeks as a 60-minute single intravenous infusion. Doses exceeding 800 mg per infusion are not recommended. Development of a preparation of tocilizumab for subcutaneous administration is under way.

Efficacy

An early double-blind, placebo-controlled, randomized clinical trial revealed statistically significant ACR20 responses with 10 mg/kg and 5 mg/kg single infusions of tocilizumab when given to patients with active RA with no concomitant DMARDs.^{144,146} Substantial decreases in measures of the acute phase response, including the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) concentration, were seen with 5 and 10 mg/kg as early as 1 week and were largely sustained through week 4. Larger phase II studies tested tocilizumab monotherapy, given at a dose of 4 mg/kg or 8 mg/kg intravenously every 4 weeks over 3 months, to patients with relatively refractory and active RA. Most individual measures of arthritis activity improved to a statistically significant level by week 4, and the extent of response continued to improve through 12 weeks. Sustained clinical responses were maintained for a considerable number of patients over 5 years of an open-label follow-up period.¹⁴⁷ In a large European study known as CHARISMA, patients with active RA despite being on MTX for at least 6 months were randomized to receive tocilizumab 2, 4, or 8 mg/kg every 4 weeks alone or in combination with their existing MTX. Another group received MTX alone. Tocilizumab alone at doses of 4 and 8 mg/kg resulted in improvement in ACR20; however, patients remaining on concomitant MTX, together with

tocilizumab, achieved statistically significant improvement compared with those given MTX alone at 16 weeks.¹⁴⁸ The ability of treatment with tocilizumab to alter the progression of joint damage was first assessed in patients with relatively early RA in a study called SAMURAI.¹⁴⁹ Therapy with tocilizumab was shown to have a beneficial effect on the progression of radiographic joint damage defined by total Sharp score, in addition to improvements in clinical and functional status.

Tocilizumab has been studied in series of multinational phase III clinical trials involving more than 4000 patients. In the OPTION trial, moderate to severe RA patients who were methotrexate-inadequate responders received 4 mg/kg or 8 mg/kg tocilizumab or placebo every 4 weeks. Fifty-nine percent and 48% of patients who received tocilizumab 8 mg/kg and 4 mg/kg plus methotrexate, respectively, achieved ACR20 at week 24, compared with 27% of patients who received placebo plus methotrexate. Patients in the placebo and 4 mg/kg groups switched to the 8 mg/kg group (rescue therapy), and by week 24, all patients receiving tocilizumab had significantly better responses in all core set values, including DAS28, HAQ, pain visual analogue scale (VAS), and global VAS.¹⁵⁰ In the TOWARD trial, patients with active disease, despite being on stable doses of DMARDs (the most common being MTX) were randomized to receive monthly 8 mg/kg tocilizumab or placebo infusions. At 24 weeks, the tocilizumab group showed significantly improved ACR20 response rates and DAS28 scores, as well as HAQ and fatigue scores.¹⁵¹ The AMBITION trial included patients who were methotrexate-naïve or who had discontinued methotrexate for reasons other than lack of efficacy or toxicity. Seventy percent of patients who received tocilizumab 8 mg/kg achieved ACR20 at week 24, compared with 53% of patients receiving methotrexate alone. ACR50 and -70 response rates, HAQ scores, and DAS28 remission were also superior in comparison with the MTX group.^{9,152} The efficacy of tocilizumab for the treatment of patients who had an inadequate clinical response or were intolerant to one or more anti-TNF agents was evaluated in a rheumatoid arthritis study in anti-TNF failures (RADIATE). Fifty percent and 30% of patients who received tocilizumab 8 mg/kg or 4 mg/kg + methotrexate, respectively, achieved ACR20 at week 24, compared with 10% of patients who received placebo plus methotrexate. Of note, the number and type of TNF antagonists previously failed did not appear to impact the ACR20 response rate. DAS28 remission rates and function assessed by HAQ were also shown to have significantly improved in the tocilizumab groups.¹⁵³ The Tocilizumab Safety and the Prevention of Structural Joint Damage (LITHE) trial is a long-term trial designed to evaluate the efficacy of tocilizumab for preventing structural damage in patients who had an inadequate response to prior methotrexate therapy. At week 24, 56% and 51% of patients who received tocilizumab 8 mg/kg or 4 mg/kg plus methotrexate, respectively, achieved ACR20 compared with 27% of patients who received placebo plus methotrexate. Mean joint erosion, joint space narrowing, and total Genant-modified Sharp scores indicated that both tocilizumab doses were associated with significant inhibition of radiographic progression from baseline compared with that of placebo (81%, 85%, and 67% in 8 mg/kg, 4 mg/kg, and placebo groups, respectively).¹⁵⁴

Table 63-3 Adverse Effects Potentially Associated with Tocilizumab

Immunomodulatory Effects
Infections/serious infections
Target-related Effects
Increased liver enzymes
Abnormalities in lipid profiles
Neutropenia
Low platelet count
Malignancies
Demyelinating conditions
Gastrointestinal perforations
Agent-related Effects
Administration reactions
Hypersensitivity reactions

Clinical, functional, and structural remission in patients with advanced RA was demonstrated in a 52-week trial. Forty-two percent of remarkably severe RA patients with long disease duration and progressive joint damage achieved clinical remission.¹⁵⁵ Long-term treatment with tocilizumab up to 4.2 years revealed increasing numbers of patients achieving ACR50 and -70 scores, DAS28 remission, and high retention rates.¹⁵⁶

Safety

A number of safety concerns are associated with blocking a major regulatory cytokine such as IL-6. These can be grouped as general immunomodulatory effects (e.g., infection), IL-6-related effects (e.g., abnormalities in liver enzymes, lipid profiles), and finally agent-specific effects (e.g., infusion reactions) (Table 63-3).

Infections are a concern, as they are with all immunomodulatory therapies for RA. In clinical trials of tocilizumab, the occurrence of infection appears compatible with that of other approved biologic agents. Although the overall infection rate with tocilizumab monotherapy was comparable with rates in methotrexate monotherapy groups, the incidence of overall infection was slightly higher with concomitant DMARD therapy. The most commonly reported infections (5% to 8%) were upper respiratory infections and nasopharyngitis. A similar incidence of serious adverse events (5%) was generally observed across study groups. Serious infections occurred more often in higher-dose groups as compared with the placebo group. Cellulitis, pneumonia, diverticulitis, gastroenteritis, and herpes zoster were the most common infections noted. Only rare cases of opportunistic infection have been reported.^{148-150,156}

Transient elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were commonly observed in tocilizumab-treated patients. Elevations were more apparent immediately following infusions, potentially reflecting blockade of the antiapoptotic properties of IL-6 in hepatocytes. An increase in ALT levels to three or more times the upper limit of normal was noted in 5% to 6.5% of patients who received tocilizumab and concomitant DMARD therapy. These rates were 1.5% and 2.1% in patients who received only DMARD or only tocilizumab, respectively.^{148,150-152} To date, elevated transaminases have

not been associated with reduced liver function or serious adverse events.^{142,148,151}

Lipid profiles were altered in the tocilizumab group compared with placebo. Tocilizumab was associated with increases in all lipid levels, including total cholesterol and its fractions, low-density lipoprotein (LDL) cholesterol, and high-density lipoprotein (HDL) cholesterol. Increases in these parameters were noted by the first assessment at 6 weeks and remained elevated through the clinical trials. Despite elevations in these parameters, clinical cardiovascular events have not increased in clinical trials. Mean increases in the 8 mg/kg tocilizumab plus DMARD group were 30.9 mg/dL (total cholesterol), 21.7 mg/dL (LDL cholesterol), 4.3 mg/dL (HDL cholesterol), and 30.1 mg/dL (triglycerides).^{150,151}

A higher proportion of patients receiving tocilizumab had a decrease in neutrophil counts (29%) in comparison with patients who were not receiving this drug (4%). The drop in neutrophil counts was generally mild (grade 1, according to the common toxicity criteria, i.e., 1500 to 2000 cells/mm³ or more) to moderate (grade 2, 1000 to 1500 cells/mm³) in severity and reversed with discontinuation of treatment. To date, no clear association between low neutrophil counts and infection-related adverse events has been noted.^{8,144,150,151}

Treatment with tocilizumab was associated with a reduction in platelet counts. The decrease in platelet counts was below the lower limit of normal and was reported in 8% to 9% of patients receiving tocilizumab with or without MTX. However, no serious bleeding incidents occurred. Only isolated cases of epistaxis and hemoptysis were reported in patients with moderate to severe thrombocytopenia.

Rare events of gastrointestinal perforation have been reported in clinical trials, primarily as complications of diverticulitis. The overall rate of gastrointestinal perforation was 0.26 event per 100 patient-years. Most patients who developed gastrointestinal perforations were taking concomitant nonsteroidal anti-inflammatory medications (NSAIDs), corticosteroids, or methotrexate. Patients presenting with new-onset abdominal symptoms therefore should be evaluated promptly for early identification of gastrointestinal perforation.

Because tocilizumab is a humanized antibody, infusion-related adverse events might be expected. Adverse reactions associated with the infusion were reported to be 8% and 7% in patients receiving 4 mg/kg and 8 mg/kg tocilizumab together with MTX. The most commonly reported adverse events were hypertension during the infusion and headache and skin reactions within 24 hours after the infusion. These reactions did not result in termination of treatment. Antibodies to tocilizumab were detected in a small group of patients, and very few were associated with medically significant hypersensitivity reactions that led to withdrawal. The development of antibodies and of infusion reactions may be greater among patients receiving the lower dose of tocilizumab.

Rates of malignancy were similar in the tocilizumab- and DMARD-treated groups. Rare cases of demyelinating disorders were reported in clinical trials. Long-term experience with tocilizumab will determine the actual risk of developing these entities; however, caution needs to be exercised

in patients with any risk factors for malignancy or demyelinating disorders.

A systematic literature search on six published randomized controlled trials that assessed the risk of adverse events with tocilizumab revealed that tocilizumab in combination with MTX as a treatment for RA is associated with a small but significantly increased risk of adverse events, which is comparable with that of other biologics. The risk of infection was significantly higher in the 8 mg/kg combination group compared with controls (odds ratio [OR], 1.30; 95% confidence interval [CI], 1.07 to 1.58). No increased incidence of malignancy, tuberculosis reactivation, or hepatitis was seen.¹⁵⁷

Drug Interactions

Inhibition of IL-6 may affect cytochrome P450 substrates. In vivo studies showed that omeprazole and simvastatin levels decreased by 28% and 57% 1 week after tocilizumab infusion. Upon initiation or discontinuation of tocilizumab, drugs with a narrow therapeutic margin such as warfarin or drug concentrations of certain drugs such as cyclosporine should be closely monitored.

Tocilizumab has not been studied, and its use should be avoided, in combination with biologic DMARDs such as TNF blockers, IL-1 blockers, anti-CD20 monoclonal antibodies, and co-stimulation blockers.

It is recommended that live vaccines should not be given concurrently with tocilizumab because clinical safety has not been established. It would be desirable for patients to be brought up to date on all recommended vaccinations before treatment with tocilizumab is initiated.

Monitoring

Patients should be evaluated for tuberculosis and other infections before treatment with tocilizumab is begun. Anti-tuberculosis therapy should be initiated before tocilizumab is started in patients with active tuberculosis.

It is not recommended to initiate tocilizumab treatment in patients who have ALT and AST levels greater than 1.5 times the upper level of normal or any evidence of liver disease. For all patients, liver function tests should be repeated initially every 4 to 8 weeks during tocilizumab treatment. When the ALT or AST level is between one and three times the upper level of normal, the dose of tocilizumab or concomitant DMARD should be adjusted. For persistent increases in this range, the tocilizumab dose should be modified. If the ALT or AST level is greater than three to five times the upper level of normal, tocilizumab should be interrupted until the level falls below three times the upper level of normal. For ALT or AST elevations greater than five times the upper level of normal, the drug should be discontinued.

Patients receiving tocilizumab should have lipid levels monitored with a goal toward maintaining levels within the target ranges of National Cholesterol Education Program Adult Treatment Panel III or local guidelines. Patients should be managed with lipid-lowering agents if appropriate.

Caution should be exercised when tocilizumab is initiated in patients with a very low neutrophil count at

baseline, and all patients should have their absolute neutrophil count (ANC) monitored 4 to 8 weeks after the first infusion. It has been recommended that tocilizumab should not be administered to patients with ANC values less than 2000 cells/mm³. If the ANC falls to between 500 cells/mm³ and 1000 cells/mm³, drug therapy should be discontinued until the ANC reaches above 1000 cells/mm³.

It is not recommended to initiate tocilizumab treatment in patients with a platelet count below 100,000/mm³. Treatment with tocilizumab should be interrupted if the platelet count falls to below 50,000/mm³. Platelets should be monitored every 3 to 8 weeks.

Pregnancy and Breastfeeding

No adequate and well-controlled studies have been conducted in pregnant women. Therefore tocilizumab is a Pregnancy Category C drug and should be used only if potential benefits justify potential risk to the fetus. It is not known whether tocilizumab is excreted in human milk or is absorbed after oral ingestion.

SUMMARY

Treatment of patients with RA with inhibitors of key pro-inflammatory cytokines TNF, IL-1, and IL-6 is a compelling example of effective targeted biologic therapy. Treatment with these agents, particularly TNF inhibitors, has substantially improved the signs and symptoms of disease; for many patients, quality of life has been improved, the progression of joint damage has been inhibited, and disability has been averted. The success of this approach has “raised the bar” for the goals of treating this pernicious disease and has reinvigorated research aimed at further refinements of therapy. It has also stimulated research into the potential utility of inhibitors of additional cytokines such as IL-6, IL-15, and IL-18 and other components of the immune system relevant to autoimmune disease.

A number of questions remain regarding the optimal use of these drugs. Longer-term safety data will allow clinicians to more fully assess the risk-benefit ratio for individual patients. Given uncertainties regarding the long-term safety of these drugs and the heterogeneity of clinical responses, research defining the populations of patients expected to derive the greatest benefit with the least toxicity is critical. For example, ongoing research assessing genetic polymorphisms or proteomic or glycomic differences among treated patients could optimize efficacy while minimizing toxicity. This is also relevant from a cost standpoint. Although the acquisition costs of these agents are relatively high, data supporting their cost-effectiveness, including gains in employment and reduced hospitalizations, are emerging.¹⁵⁸

The success observed with these biologic therapies has raised additional clinical questions. For example, can very early treatment with highly effective therapy, such as the combination of TNF inhibitor and MTX, truly alter the disease course? What might the optimal treatment paradigms be for various rheumatic diseases? The success of the TNF inhibitors has also generated substantial interest in targeting this cytokine by alternative approaches, including inhibition of key regulatory factors, such as p38 mitogen-activated protein (MAP) kinase and NFκB. Advances in

biopharmaceuticals could generate agents that possess desirable characteristics in terms of pharmacokinetics, immunogenicity, adverse effects, ease of administration, and cost. These developments should eventually allow clinicians to maximize the use of these novel therapies and achieve clinical benefits that previously were considered unattainable.

KEY POINTS

Rituximab is an effective biologic therapy across the spectrum of rheumatoid arthritis (RA)-but with greatest benefit in seropositive patients. Clinical trials in active, established RA confirm that a single cycle of rituximab produces an enduring clinical response comparable with that observed in tumor necrosis factor (TNF) blockade.

Current data suggest that the most appropriate interval between rituximab courses is 6 to 12 months. Repeat treatment produces responses that equal or exceed those from the first course of treatment, with a comparable duration of effect.

Rituximab has an acceptable safety record in RA trials, but infusion reactions of variable severity can occur; most are mild to moderate. Frequency and severity are reduced by the administration of intravenous methylprednisolone before rituximab infusions.

Clinical trials in active, established RA confirm that abatacept can result in a meaningful clinical response within 16 weeks, although additional improvement may occur for a year or beyond.

Abatacept represents an effective biologic therapy with acceptable safety across the spectrum of RA-patient populations. For a majority of those achieving clinical responses in the first 6 months, sustained clinical responses that follow may be incremental up to 2 years of treatment. A newer subcutaneous formulation is equally effective.

The benefit-to-risk profile of abatacept may be most optimal when introduced earlier in the RA treatment paradigm.

Both rituximab and abatacept slow radiographic progression in RA.

Current uncertainties include the lack of reliable biomarkers to inform the rational choice of a biologic agent.

Cell-Targeted Biologics and Targets: Rituximab, Abatacept, and Other Biologics

PETER C. TAYLOR

biologic therapeutics targeting tumor necrosis factor (TNF), particularly when used in combination with oral methotrexate, have enjoyed notable success in suppressing inflammation and markedly inhibiting the progression of structural damage previously thought to be an unavoidable characteristic of RA.^{4,5} However, despite the unprecedented clinical and commercial successes of TNF inhibitors, their availability is restricted by high costs. In addition, a substantial proportion of RA patients fail to demonstrate significant clinical responses.

An entirely different treatment approach to the blockade of proinflammatory cytokines is the targeting of cells implicated in the persistence of RA. It is believed that immune responses drive the disease process in RA, and because chronicity is a hallmark of the RA phenotype, it presumably reflects the persistence of immunologic memory, induced and maintained by the adaptive immune system. In particular, T and B cells develop highly specific receptors and, after stimulation, expand enormously in number and then persist for long periods. If this is true of aberrant immune responses that lead to disease, then T and B cells represent rational targets for immune intervention. The focus of this chapter is on biologics with specificity for cellular targets, namely cell surface molecules associated with B cell subsets, most notably CD20, and co-stimulation molecules expressed on antigen-presenting cells that recognize cognate ligands on T cells. The particular emphasis is on two drugs that have become an accepted part of the pharmacologic armamentarium for RA treatment: rituximab and abatacept. Rituximab (Rituxan, Genentech Inc. and Biogen Idec Inc.; MabThera, F-Hoffman LaRoche Ltd.) is an antibody that selectively depletes a B cell subset expressing the CD20 antigen. Other biologics targeting this antigen that have been in clinical trials are the humanized monoclonal antibody ocrelizumab and fully human monoclonal antibody ofatumumab. Abatacept (Orencia, Bristol-Myers Squibb) is a fusion protein that selectively modulates a co-stimulatory signal necessary for T cell activation. Rituximab is approved in the United States and Europe for use in combination with methotrexate to reduce the signs and symptoms of RA in adult patients who have moderately to severely active disease and have failed one or more anti-TNF drugs. Abatacept is the first selective co-stimulation modulator to be approved in the United States and Europe for the treatment of RA patients with an inadequate response to other non-biologic or biologic disease-modifying antirheumatic drugs (DMARDs).

As appreciation of the gravity of the social and economic burden imposed by rheumatoid arthritis (RA) has grown, so has the recognition that more favorable clinical outcomes are achieved when synovitis is optimally suppressed. The evidence is particularly compelling early in the course of RA, when intervention with disease-modifying combination therapy results in improved remission rates and increased clinical and radiographic benefits.¹⁻³ The armamentarium of potential therapeutics has also grown with the identification of relevant disease molecules. Of these,

TARGETING B CELLS

KEY POINT

B cells are major contributors to RA pathogenesis, but their precise roles in the induction and maintenance of pathogenic immune activation remain poorly understood.

The role of B cells in the pathogenesis of RA is not fully understood. Nonetheless, there are many known B cell functions of likely relevance including their role in antigen presentation, secretion of proinflammatory cytokines, production of rheumatoid factor (RF) and thus immune complex formation, and co-stimulation of T cells. Of note, immune complexes are an important trigger to the production of TNF and other proinflammatory cytokines. B cells are also implicated in the process of ectopic lymphoid organogenesis in the rheumatoid synovium.

B cells arise from stem cells in the bone marrow, where they acquire an antibody receptor bearing a unique variable region. A number of maturation and activation steps take place as the B cells migrate from the marrow compartment, through blood, and to perifollicular germinal centers and memory compartments in lymphoid tissue, before returning to the marrow as mature plasma cells.⁶ Successful maturation and survival of cells are tightly regulated and dependent on a number of trophic signals delivered via cell surface ligands such as vascular cell adhesion molecule-1 (VCAM-1) and soluble factors such as B lymphocyte stimulator (BLyS).^{7,8}

In the late 1990s, Edwards and colleagues^{9,10} suggested that the (assumed) underlying autoreactive response in RA might be driven by self-perpetuating B cells and that the initiation of inflammation results from ligation of the low-affinity immunoglobulin G (IgG) receptor FcγRIIIa by immune complexes. An attractive feature of this hypothesis, particularly in seropositive patients, is that it might account for the tissue tropisms of disease expression in the RA syndrome complex because FcγRIIIa is expressed in high levels in synovium and other extra-articular tissues that may be involved in RA. RF-producing cells can capture antibodies bound to antigen before antigen internalization by endocytosis and subsequent presentation of peptide fragments to a T cell, with provision of T cell help to the B cell. Edwards and colleagues¹¹ also proposed that such RF-producing B cells might become self-perpetuating by an amplification signal arising from co-ligation of the B cell receptor and small immune complexes formed by IgG RF bound to the complement component C3d, providing a survival signal. In contrast, co-ligation of certain other B cell surface receptors with the B cell receptor may provide a negative survival signal. In the rare event that self-perpetuating, autoreactive B cells arise, having escaped normal regulatory mechanisms, this theory predicts that a B cell depletion strategy would remove the autoreactive B cell clones and their antibody products. Because CD20 is not internalized and is highly expressed on a range of B lineage cells including pre-B cells, immature B cells, activated cells, and memory cells, but is not found on stem, dendritic, or plasma cells (Figure 64-1), it is an ideal target for B cell depletion by monoclonal antibodies. The hypothesis that B cells represent a therapeutic target in RA is also

CD20 expression during the maturation of B cells

Figure 64-1 Expression of the CD20 antigen on B lineage cells.

being tested in the clinic using other strategies for B cell inhibition, as discussed later.

The CD20 antigen is located in the B cell membrane, with 44 amino acids exposed to the extracellular space. Its function is unknown, although it may have a role in cell signaling or in calcium mobilization.¹² Interestingly, CD20 knockout mice do not have a clear-cut phenotype or obvious B cell defect.¹³ CD20⁺ B cells represent a prominent population in the rheumatoid synovial tissue in the majority of patients.

Rituximab in Rheumatoid Arthritis

KEY POINTS

Rituximab is a depleting chimeric monoclonal antibody lytic for a population of B cells expressing CD20.

Rituximab is an effective biologic therapy across the spectrum of RA-patient populations.

It appears to have greatest benefit in seropositive patients.

Rituximab given as two infusions of 1 g each slows radiographic progression in RA.

Rituximab has an acceptable safety record in RA trials, but infusion reactions of variable severity can occur; most are mild to moderate. Frequency and severity are reduced by the administration of intravenous methylprednisolone before rituximab infusions.

A rare complication in RA patients treated with rituximab is progressive multifocal leukoencephalopathy. Because of the increase in relative risk, patients should be counseled appropriately.

Repeat treatment produces clinical responses that equal or exceed those from the first course of treatment, with a comparable duration of effect.

Other approaches to B cell–targeted therapy are under investigation, including antibodies that target other B cell surface antigens, neutralization of B cell stimulating factors, and signaling molecules that participate in B cell activation.

Rituximab is a chimeric mouse-human monoclonal antibody directed against the extracellular domain of the CD20 antigen. It initiates complement-mediated B cell lysis and may permit antibody-dependent, cell-mediated cytotoxicity when the Fc portion of the antibody is recognized by corresponding receptors on cytotoxic cells. Rituximab may also

Table 64-1 Percentage of Patients Achieving Responses at 24 Weeks in the DANCER and REFLEX Studies

Study	Drug Regimen	ACR20	ACR50	ACR70

ACR, American College of Rheumatology; DANCER, Dose-ranging Assessment: International Clinical Evaluation of Rituximab in Rheumatoid Arthritis; REFLEX, Randomized Evaluation of Long-term Efficacy of Rituximab in Rheumatoid Arthritis.

initiate apoptosis¹⁴ and influence the ability of B cells to respond to antigen or other stimuli.¹⁵ Rituximab initially found a role in the clinic as a single-agent treatment for relapsed or refractory low-grade or follicular CD20⁺ B cell non-Hodgkin's lymphoma, for which it was approved. For this reason, there was a wide experience with rituximab in hematologic oncology before clinical trials in RA and its recent approval in the United States and Europe for the treatment of TNF inhibitor–refractory RA patients with active disease.

Following rituximab administration, rapid B cell depletion takes place in peripheral blood and conventional methods for measurement of peripheral blood B cells by means of CD19 expression detect no cells at all in the majority of cases. Investigation of synovial tissue from patients with RA treated with rituximab reveals a decrease in synovial B cells and plasma cells in most but not all patients.^{16,17} These findings raise the possibility that there might be as yet poorly understood rescue mechanisms in the inflamed synovium providing survival niches or, alternatively, that some B cells may have an inherent resistance against depletion.

Analysis of peripheral blood memory B cells before depletion and during and after reconstitution seems to be predictive of clinical outcome, with patients showing early relapses having substantially higher IgD⁺ and IgD-CD27⁺ memory B cell numbers and proportion during B cell recovery.¹⁸ In addition to these cellular biomarkers, serologic parameters have been analyzed. Decreases in RF or anti-citrullinated protein antibody serum levels are reported to be associated with B cell depletion,¹⁹ but further studies are necessary to determine the relationships between these serologic changes and clinical response.

Clinical Studies

Clinical trials in active, established RA confirm that a single cycle of rituximab given as two infusions of 1 g each, together with once-weekly oral methotrexate, produces an enduring clinical response. A treatment cycle of two infusions of 500 mg is also efficacious but may result in a lower proportion of patients demonstrating more robust clinical responses.

The findings of early clinical studies of B cell depletion therapy in patients with active RA using rituximab in a number of different treatment regimens suggested an encouraging benefit with an acceptable safety profile and pointed to a possible therapeutic role for rituximab in RA.²⁰⁻²² Confirmation of benefit, however, required a randomized, double-blind, controlled study. In a phase IIa

study, the efficacy of rituximab in active RA was tested in 161 patients who had failed to respond adequately to methotrexate at a dose of at least 10 mg a week for a minimum of 16 weeks.²³ Patients were assigned to one of four treatment regimens: 1-g infusion of intravenous rituximab alone on days 1 and 15, methotrexate alone as a comparison arm, intravenous rituximab with cyclophosphamide infusions at a dose of 750 mg on days 3 and 17, or rituximab and methotrexate. All patients received 100 mg methylprednisolone just before each treatment, in addition to prednisolone 60 mg daily on days 2, 4, 5, 6, and 7 and 30 mg daily on days 8 to 14. The primary end point was the proportion of patients achieving an American College of Rheumatology 50% improvement criteria (ACR50) response at week 24, and exploratory analyses were undertaken at week 48. At week 24, a significantly greater proportion of patients achieved an ACR50 in the rituximab and methotrexate combination group (43%; $P = .005$) and in the rituximab and cyclophosphamide combination group (41%; $P = .005$) than in the group receiving methotrexate as monotherapy (13%) (Table 64-1). Thirty-three percent of the patients receiving rituximab alone achieved an ACR50 response, but this failed to reach statistical significance compared with methotrexate alone ($P = .059$). In all the rituximab groups, the mean change from baseline in disease activity score was significant compared with methotrexate alone.

At 48 weeks, exploratory analyses indicated ACR50 and ACR70 responses in 35% and 15%, respectively, of patients in the rituximab and methotrexate group—significantly greater than the 5% and 0% responding at the corresponding levels in the methotrexate group. In the rituximab and cyclophosphamide treatment arm, 27% of patients achieved an ACR50 response.

Rituximab treatment was associated with near-complete peripheral blood B cell depletion, persisting throughout the 24-week period of the primary analysis. Patients in the rituximab groups had a substantial and rapid reduction in the concentration of RF in serum, but despite peripheral B cell depletion, immunoglobulin levels did not change substantially.²³ The overall incidence of infection was similar in the control and rituximab groups at 24 and 48 weeks. By week 24, four patients in the rituximab groups had suffered a serious infection, as well as one in the control group. Two additional serious infections were reported during the extended 48-week period in the rituximab groups, one of which was fatal. Infusion reactions of any type were reported in 36% of patients receiving rituximab and 30% of patients receiving placebo, although most were characterized as mild or moderate. The reactions included hypotension,

hypertension, flushing, pruritus, and rash. In the rare case of severe reactions, it has been suggested that a cytokine release syndrome associated with marked cell lysis following rituximab might be a contributing factor.

In summary, the findings of the phase IIa study indicated that a single course of treatment with rituximab, particularly in combination with methotrexate, produces an enduring response in patients with severe, seropositive, active RA. Further, treatment with rituximab was well tolerated, with a favorable safety profile over 48 weeks of follow-up.

To follow up the phase IIa study, a phase IIb study was undertaken to examine the efficacy and safety of rituximab at different doses, with or without glucocorticoids, in patients with active RA resistant to DMARDs including biologics. The findings of this phase IIb study, known as the DANCER (Dose-ranging Assessment: International Clinical Evaluation of Rituximab in RA) trial, were reported in 2006.²⁴ The researchers recruited 465 patients with active disease who had to have failed to respond to at least one DMARD other than methotrexate, but no more than five, or failed to respond to biologic response modifiers, and they had to have been treated with methotrexate as a single DMARD for at least 12 weeks, with 4 weeks of stable therapy at a dose of at least 10 mg a week. All other DMARDs were withdrawn at least 4 weeks before randomization—8 weeks for infliximab, adalimumab, and leflunomide. Patients were randomized to receive either placebo infusions or rituximab at a dose of 500 mg or 1 g on days 1 and 15, together with one of three glucocorticoid options: glucocorticoid placebo, 100 mg of intravenous methylprednisolone before each rituximab infusion, or

100 mg of methylprednisolone before each infusion in addition to an oral corticosteroid. The results at 24 weeks confirmed the significant efficacy of a single course of rituximab in active RA when combined with methotrexate. This benefit was independent of glucocorticoids, although methylprednisolone on day 1 reduced the incidence and severity of first rituximab infusion reactions by about one-third (Figure 64-2). Both rituximab doses were efficacious. At the lower dose, 55% of recipients achieved ACR20 responses, as did 54% of those at the higher rituximab dose—in both cases, significantly greater than the 28% of those receiving placebo infusions. Similarly, significantly higher proportions of patients achieved ACR50, ACR70 (see Table 64-1), and European League Against Rheumatism (EULAR) good responses at 24 weeks at both rituximab doses compared with patients receiving placebo infusions (Figure 64-3). At the most stringent ACR70 response level, the difference in the percentage of responders in the placebo, lower-dose rituximab, and higher-dose rituximab groups was most marked at the higher rituximab dose of 1 g 2 weeks apart (5%, 13%, and 20%, respectively; $P < .05$). Adverse events reported up to 24 weeks were largely infusion related, particularly at the time of the first infusion.

A trial, known by the acronym REFLEX (Randomized Evaluation of Long-term Efficacy of Rituximab in RA), was designed to determine the efficacy and safety of rituximab when used in combination with methotrexate in patients with active RA who have an inadequate response to one or more anti-TNF therapies because of either lack of efficacy (90% of patients recruited) or toxicity (10% of patients recruited); in addition, all patients had

Figure 64-2 DANCER infusion reactions. Chart showing the occurrence of infusion reactions in the DANCER (Dose-Ranging Assessment: International Clinical Evaluation of Rituximab in RA) trial, a phase IIb study undertaken to examine the efficacy and safety of rituximab at two doses, with or without glucocorticoids (GCs), in patients with active rheumatoid arthritis resistant to disease-modifying antirheumatic drugs including biologics. Patients were randomized to receive either placebo infusions or rituximab at a dose of 500 mg or 1 g on days 1 and 15, together with one of three glucocorticoid options: glucocorticoid placebo, 100 mg intravenous methylprednisolone before each rituximab infusion, or 100 mg methylprednisolone before each infusion in addition to oral corticosteroid. Pretreatment with methylprednisolone before rituximab infusion reduced the incidence and severity of reactions by about one third. (Based on data in Emery P, Fleischmann R, Filipowicz-Sosnowska A, et al [for the DANCER study group]: The efficacy and safety of rituximab in patients with active rheumatoid arthritis despite methotrexate treatment: results of a phase IIb randomized, double-blind, placebo-controlled, dose-ranging study, *Arthritis Rheum* 54:1390–1400, 2006.)

Figure 64-3 DANCER changes in DAS28 at 6 months. Mean changes in disease activity score (DAS28) from baseline in the phase IIb DANCER study were significantly greater in patients treated with two rituximab infusions 2 weeks apart at either 500 mg or 1 g each, compared with placebo infusions ($P < .0001$). (Based on data in Emery P, Fleischmann R, Filipowicz-Sosnowska A, et al [for the DANCER study group]: The efficacy and safety of rituximab in patients with active rheumatoid arthritis despite methotrexate treatment: results of a phase IIb randomized, double-blind, placebo-controlled, dose-ranging study. *Arthritis Rheum* 54:1390–1400, 2006.)

radiographic evidence of at least one joint with definite erosion attributable to RA (Figure 64-4). The recruited cohort comprised 520 patients with mean disease duration of 12 years on a background regimen of methotrexate 10 to 25 mg once a week. After a washout period during which other DMARDs and anti-TNF drugs were withdrawn, patients were randomized to receive a single course of 1 g rituximab or placebo infusions on days 1 and 15. All patients were given 100 mg intravenous methylprednisolone before each infusion and a brief course of oral prednisolone between the two doses: 60 mg daily from days 2 to 7 and 30 mg daily from days 8 to 14.²⁵

Of the patients assigned to rituximab, 82% completed 6 months, compared with only 54% of the patients assigned to placebo. The major reason for study withdrawal was lack of response, reported in 40% of the placebo group and 12% in the rituximab group. At 6 months, significantly more patients receiving rituximab achieved ACR20, ACR50, and ACR70 responses than did those receiving placebo: 51%, 27%, and 12%, respectively, on rituximab, versus 18%, 5%, and 1% of those on placebo (see Table 64-1). In terms of change in disease activity score (DAS28), intention-to-treat analyses showed that in patients administered placebo infusions, the reduction from baseline was 0.34, less than the 0.6-point reduction considered to be clinically meaningful; in contrast, the reduction was 1.83 in the rituximab group.²⁵

The ACR response evaluates RA treatment on the basis of a 20%, 50%, or 70% improvement in five of seven core components. However, from the patient's perspective, determining the actual benefit of an ACR20 improvement is not straightforward. In the REFLEX study, there were significantly greater improvements in all components of the ACR core measures in the rituximab group. Rituximab demonstrated a clinically meaningful benefit for RA patients in physical function evaluated by a health assessment questionnaire (HAQ) in all nonoverlapping ACR response categories. In the active treatment arm, both clinical and subjective parameters of the ACR core components contributed to the assignment of an ACR20 response, whereas in the placebo group, the subjective parameters dominated.²⁵

In the REFLEX study, following a single treatment course, the maximal clinical response to rituximab plus methotrexate was observed at 24 weeks. After this time, patients were eligible to exit the study and receive further rituximab treatment on the basis of clinical need. Of the patients in the rituximab plus methotrexate group, 37% (114 of 308) remained in the study over 48 weeks, indicating continued

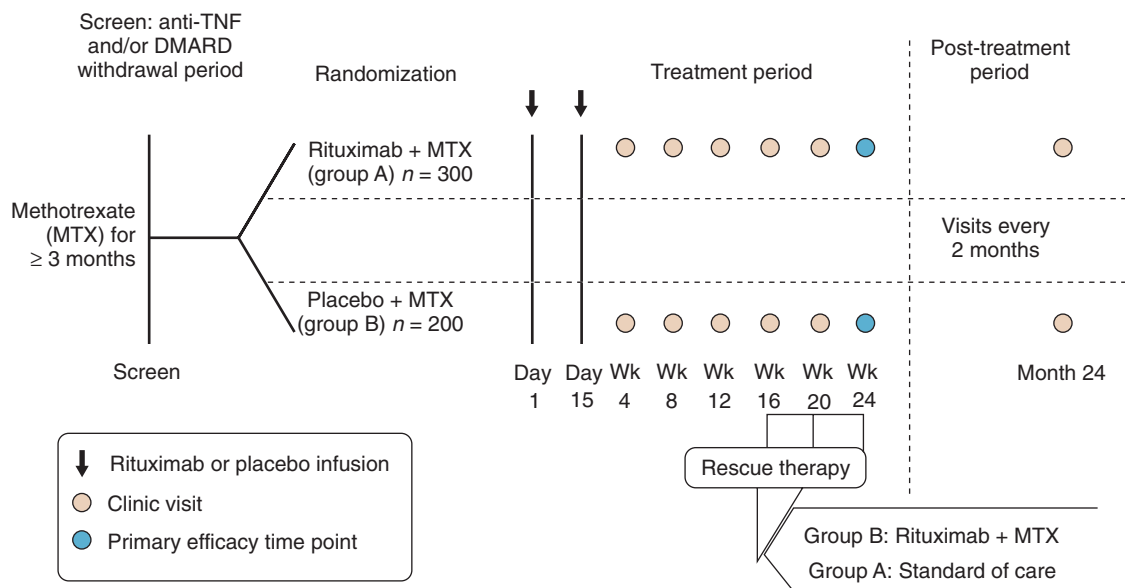

Figure 64-4 REFLEX study design. Scheme illustrating the phase III REFLEX (Randomized Evaluation of Long-term Efficacy of Rituximab in RA) study designed to determine the efficacy and safety of rituximab when used in combination with methotrexate (MTX) in patients with active rheumatoid arthritis who have an inadequate response to one or more anti-tumor necrosis factor (TNF) therapies. DMARD, disease-modifying antirheumatic drug.

clinical benefit after the single initial treatment course. The majority of patients who withdrew did so to receive further courses of rituximab between weeks 24 and 48 of the study. In contrast, 89% of the placebo plus methotrexate group (185 of 209) withdrew before week 48.²⁶

Another recently reported phase III study known by the acronym SERENE (Study Evaluating Rituximab's Efficacy in methotrexate iNadequate rEsponders) confirmed the benefits of rituximab in RA patients receiving concomitant methotrexate who had active disease at baseline despite methotrexate therapy and who had not received prior biologic therapy.²⁷ Patients were randomized to receive either placebo or rituximab at one of two doses, 2×500 mg and 2×1000 mg. From week 24, in an open-label extension, those patients in the rituximab arms failing to achieve remission as assessed by DAS28 received a second course of rituximab and all placebo patients were treated with the lower rituximab dose. At week 24, a significantly greater proportion of patients receiving rituximab 2×500 mg or 2×1000 mg + methotrexate achieved the primary end point of an ACR20 response versus patients receiving placebo plus methotrexate (54.5% and 50.6% vs. 23.3%, respectively; $P < .0001$). By week 48 approximately 90% of patients in all treatment groups had received a second course of treatment. The majority of these repeat treatments (82% to 88%) were given by week 30.

In rituximab-treated patients, efficacy outcomes at week 48 were comparable with those at week 24; additionally, improvement was observed for several clinically important end points including an approximate doubling in the proportion of patients achieving low disease activity (DAS28 < 3.2) in the rituximab (2×1000 mg) plus methotrexate dose group from week 24 to week 48. The safety profile of rituximab in the SERENE study was comparable with that observed in earlier trials, with infusion-related reactions—most nonserious—at the time of first infusion being the most common adverse event. Reductions in immunoglobulin levels were observed, predominantly IgM, but with mean levels remaining within normal limits. No relationships between infectious complications and reduced immunoglobulin levels were observed, and in fact the rate of infection observed in patients receiving rituximab plus methotrexate was low and comparable with patients receiving methotrexate alone over the placebo-controlled 24-week period. This low rate of serious infection continued throughout the full 48-week period, with no obvious difference between the rituximab doses.

Results from the IMAGE study, which included 748 patients without prior use of either biologics or methotrexate, were recently reported. In this group, high-risk patients who had baseline high DAS28 scores or high CRP were found to have greater DAS28 improvement at week 52 if they received rituximab in addition to methotrexate.²⁸

Disease Modification

The extraordinary success of TNF blockade in inhibiting structural damage to joints in patients with RA has set a new standard to which all new biologics must aspire. Inhibition of structural joint damage by rituximab in patients with RA and a previous inadequate response to TNF inhibitors from the REFLEX study was first described over a 1-year

period²⁹ with a subsequent demonstration that the initial effects of rituximab are maintained over an extended interval of 2 years, with all measures of joint damage significantly improved compared with placebo plus methotrexate.³⁰ At week 56,²⁹ the mean change in Genant-modified Sharp score in the placebo plus methotrexate arm was 2.31, compared with 1.0 in the rituximab plus methotrexate group ($P = .0043$). Significant differences were also reported for joint space narrowing and bone erosions. At week 104, significantly lower changes in total Genant-modified Sharp score (1.14 vs. 2.81; $P < .0001$), erosion score (0.72 vs. 1.80; $P < .0001$), and joint space narrowing scores (0.42 vs. 1.00; $P < .0009$) were observed with rituximab plus methotrexate versus placebo plus methotrexate.³⁰ Importantly, within the rituximab group, 87% who had no progression of joint damage at 1 year remained nonprogressive at 2 years. Thus these data confirm that rituximab plus methotrexate has the benefit of sustained inhibition of joint damage progression in patients with RA and a previously inadequate response to TNF inhibitors.

Radiographic outcomes were recently reported for a phase III study designed to determine the efficacy of rituximab in the prevention of joint damage and its safety in combination with methotrexate in the context of patients initiating treatment with methotrexate.²⁸ This study, known by the acronym IMAGE (International study in Methotrexate-naïve subjects investiGating rituximab's Efficacy) was a randomized, controlled, double-blind trial involving 748 methotrexate-naïve patients assigned to receive rituximab at doses of either 2×1000 mg or 2×500 mg every 24 weeks in combination with methotrexate or methotrexate alone. The primary end point was radiographic progression measured by total modified Sharp score at week 52. In patients treated with 2×1000 mg rituximab and methotrexate, significantly smaller change (0.359) in modified total Sharp score (mTSS) was observed compared with patients on methotrexate alone (1.079; $P = <0.001$). Furthermore, a significantly higher proportion of patients treated with MabThera and methotrexate had no progression in their joint damage over 1 year (64% vs. 53%; $P = .0309$). By week 52, 65% of these patients achieved a 50% improvement in symptoms (ACR50) while 47% had achieved a 70% improvement (ACR70), compared with 42% and 25% on methotrexate alone ($P < .0001$ for both ACR50 and ACR70 comparisons).

Safety Issues

The rapidity and magnitude of peripheral blood B cell depletion following anti-CD20 therapy raise concerns about potential adverse sequelae. The peripheral compartment recovers after many months, but repopulation is predominantly with an immature and naïve subset of B cells. But it must also be remembered that the circulation contains less than 2% of total B cells.³¹ A common concern regarding all therapies directed at B cells is the potential for toxicity related to modulation of humoral immunity. Unlike other newly introduced biologic therapies for RA, rituximab has the considerable advantage of an oncology safety database based on more than 350,000 non-Hodgkin's lymphoma patient treatments since 1997.³² The overall safety conclusions are that serious adverse events are infrequent and

often associated with well-defined risk factors such as cardiopulmonary disease or a high number of circulating cancer cells. Of note, in the lymphoma population, prolonged peripheral B cell depletion has not been associated with cumulative toxicity or increased occurrence of opportunistic infections.³³⁻³⁵ However, it cannot be assumed that the toxicity profile will be identical in distinct disease phenotypes with differing pathogenic processes.

In RA open-label,³⁶ phase II,^{23,24} and phase III²⁵ studies, although decreases in total serum immunoglobulin levels were observed in patients receiving rituximab, concentrations remained within normal limits. Of note, existing antibody titers against tetanus toxoid appear to be unaffected by a single course of rituximab treatment.³⁷ However, there is some anecdotal evidence that total serum immunoglobulin concentrations fall below the normal range in patients receiving multiple cycles of rituximab treatment over a number of years in open-label studies.¹¹ It is unclear whether this results in an increased risk of infection. In phase II studies, most adverse events were mild to moderate and associated with infusions including headache, nausea, and rigors. In a recent meta-analysis of randomized clinical trial data from three studies reporting adverse events arising after a single cycle of rituximab treatment in a total of 938 RA patients refractory to nonbiologic DMARDs or biologic anti-TNFs,²³⁻²⁵ it was calculated that the incidence of patients experiencing adverse events of all systems was not higher in the rituximab-treated patients than in the placebo groups (relative risk [RR], 1.062; 95% confidence interval [CI], 0.912 to 1.236, $P = .438$).³⁸

In the DANCER trial, adverse events associated with rituximab were largely associated with the first infusion; these occurred in 39% of patients treated with 500 mg (without steroid) and in 46% receiving 1 g, compared with 17% administered placebo infusions.²⁴ The corresponding incidence with the second infusion decreased to 5%, 8%, and 10%, respectively. Two serious infusion reactions, hypersensitivity and generalized edema, occurred on day 1. Pretreatment with methylprednisolone reduced the incidence and severity of reactions by about one-third (see Figure 64-2). Infectious adverse events (largely upper respiratory tract infections) were reported in 28% of placebo and 35% of rituximab patients. There were six serious infections: two in the placebo group, four in patients receiving 1000 mg rituximab, and none in patients receiving 500 mg rituximab. No opportunistic infections or tuberculosis reactivations were reported.

Although the overall safety record based on trial data has been favorable, with wider clinical use of biologic B cell depletion, rarer serious complications have come to light. A potential association has been reported between the biologic therapies efalizumab, natalizumab, and rituximab and the rare, progressive, and usually fatal condition progressive multifocal leukoencephalopathy (PML), a rare brain disease caused by reactivation of the JC virus.³⁹ PML has been reported in patients receiving rituximab for hematologic conditions and systemic lupus erythematosus (SLE)⁴⁰ and more recently in RA.³⁹ The cumulative incidence rate of PML in the RA population has been estimated at 1/100,000 RA admissions in an analysis limited to hospitalized patients with SLE and other rheumatic diseases (including 25 patients with RA), a majority of whom had concomitant

risk factors including human immunodeficiency virus (HIV), malignancy, or transplantation of bone marrow or another organ.⁴¹ The cumulative reporting rate of 2.2 cases of PML per 100,000 RA patients treated with rituximab is more than double the estimated frequency in RA at 2.2 (95% CI, 0.3 to 8.0).³⁹ Although the absolute risk is small, the relative risk is such that it emphasizes the importance of providing the prospective patient being considered for B cell-depleting therapy with thoughtful and balanced information about likely benefits, as well as common to rare complications.

The profound and enduring peripheral B cell depletion that accompanies use of rituximab raises a potential safety concern for those patients in clinical practice who fail to derive adequate symptomatic benefit and may then be exposed to biologic DMARDs of alternative mechanism of action at a time point before repopulation of circulating B cells can take place. Relatively little data regarding this circumstance exist to date, but there is preliminary information in 185 of 2578 RA patients who went on to receive an alternative mechanism of action biologic as documented in a safety follow-up period following participation in trials in which they had previously received rituximab.⁴² Of the 185 patients 89% remained peripherally B cell depleted at the point of commencing a new mechanism of action biologic. The rate of serious infectious events reported following rituximab but before second biologic exposure was 6.99 per 100 patient-years, comparable with the reported rate of 5.49 per 100 patient-years after exposure to a second biologic agent, the majority of which were TNF inhibitors. No fatal or opportunistic infections were observed, the nature and course of infectious complications being within expectation for RA patients on biologic therapy. In a population of methotrexate-naïve patients entering the IMAGE study,²⁸ safety data were consistent with results from previous rituximab clinical trials and further enhanced the robust safety profile. Rates of serious adverse events and serious infections were similar between the two MabThera groups and the methotrexate-only group.

RA patients, particularly those treated with immunosuppressants, are at an increased risk of infection. For this reason, vaccination is an important aspect of RA clinical management. As to whether B cell-depleting therapy could adversely affect immunization responses by suppressing the antibody response from new vaccination or reducing preformed antibody from prior vaccination has been investigated, and the findings were recently reported.⁴³⁻⁴⁵ These studies indicate that vaccine responses to some, but not all, vaccinations may be diminished in rituximab-treated patients, most strikingly in the first 4 to 8 weeks following rituximab administration.⁴³ Although prior vaccination and timing of vaccine administration after rituximab infusion may influence the ability to mount a response, there is no straightforward relationship between peripheral B cell reconstitution and response to immunization. Therefore where vaccination is indicated, it should ideally be given before rituximab treatment and avoided immediately after B cell depletion with a delay of several months. Of course, this may not be practical for vaccines with seasonal availability (such as those to influenza variants), and it must be recognized that responses to vaccination do not necessarily correlate with the risk of infection. In general, the timing

of rituximab administration must be determined according to clinical need without requirement to delay until after supplies of a seasonally variable vaccine become available and the patient has been immunized.

In a recent meta-analysis of six studies enrolling 2728 patients, nonmelanotic skin carcinoma occurred more commonly than other carcinomas in the rituximab treatment groups (0.8% in rituximab group vs. none reported in the control group). Moreover, overall incidence of malignancies was higher in the rituximab group (2.1%) compared with the control group (0.6%).⁴⁶

The safety and efficacy profile of rituximab in the treatment of RA discussed so far is based on reports from randomized placebo-controlled trials of 6 to 12 months' duration. Open-label extension studies have analyzed safety and efficacy results over multiple courses of rituximab.⁴⁷ In safety analyses based on 5013 patient-years of rituximab exposure, in a total of 2578 RA patients who received at least 1 course of rituximab, infusion-related reactions were the most common adverse event occurring in a quarter of patients during the first infusion of the initial treatment cycle, although only 1% of infusion reactions in total were considered to be of a serious nature. Importantly and reassuringly, the rates of both adverse events and serious adverse events were stable over infusion cycles, the later reported as 17.85 events per 100 patient-years (95% CI: 16.72, 19.06). Infections and serious infections over time remained stable across five treatment cycles at 4 to 6 events per 100 patient-years. There were no cases of tuberculosis, disseminated fungal infections, or other serious opportunistic infections during the analysis period. Viral reactivation is a potential concern in immunosuppressed patients. The rate of herpes zoster infections in this large series was 0.98 events per 100 patient-years, similar to that reported for other RA populations. The much more serious and rare opportunistic infection, PML occurred in a single patient who also received cancer chemotherapy and radiation. The event occurred about 18 months after the last dose of rituximab and 9 months after receiving chemotherapy and radiation. The causal relationship to rituximab, if any, is thus not entirely clear. There was no increased risk of malignancy by comparison with reference patients with RA and with the general population in the United States. Myocardial infarction was one of the most common serious adverse events reported in the longer-term analyses at a rate of 0.56 per 100 patient-years, but this is consistent with rates reported in epidemiologic studies of patients with RA.

Duration of Benefit

Among RA patients achieving clinical responses to rituximab treatment, the time to clinical relapse is heterogeneous. In some patients, relapse is closely correlated to the reappearance of peripheral blood B cells, but in others, it may be delayed by years.⁴⁸ Clinical relapse is more closely associated with increases in autoantibody levels, but better biomarkers are necessary to reliably inform optimal management strategies on an individual basis. All B cell populations are depleted following rituximab therapy. Of residual B lineage cells, more than 80% exhibit a memory or plasma cell precursor phenotype.⁴⁹ B cell repopulation occurs at a mean of 8 months after rituximab therapy and

depends on the formation of naïve B cells of an immature phenotype resembling those found in umbilical cord blood. Peripheral B cell depletion is accompanied by substantial increases in blood BLYS concentrations, which tend to fall with B cell repopulation.⁵⁰ BLYS is a naturally occurring protein required for the development of B lymphocytes into mature plasma cells. Elevated levels of BLYS in RA are believed to contribute to the production of autoantibodies. However, in cases of prolonged clinical responses to rituximab, more gradual reductions in BLYS concentrations have been observed, extending beyond the period of B cell depletion. Thus BLYS may contribute to the survival or regeneration of pathogenic, autoreactive B cells. This hypothesis predicts a potential therapeutic role for BLYS blockade in addition to B cell depletion.

Information concerning the efficacy and safety of repeated cycles of rituximab treatment has emerged from experience in clinical practice and from randomized trials. The recently reported phase III MIRROR trial (Methotrexate Inadequate Responders Randomised study Of Rituximab) was a randomized, double-blind, international study to evaluate the efficacy and safety of three dosing regimens of rituximab in combination with methotrexate in 375 patients with active RA and an inadequate response to methotrexate.^{51,52} Patients were randomized to three groups with two courses of rituximab treatment at varying doses: Group A: all courses 500 mg rituximab on days 1 and 15; repeat treatment at 24 weeks; group B: first course 500 mg rituximab on days 1 and 15; second course 1000 mg rituximab; repeat treatment at 24 weeks; group C: all courses 1000 mg on days 1 and 15; repeat treatment at 24 weeks. The primary end point was the proportion of patients achieving ACR20 at week 48. Secondary end points included ACR50, ACR70, and EULAR responses. There was a trend toward better efficacy results with the regular 2×1000 mg dose compared with the low 2×500 mg dose, and this reached statistical significance for EULAR good/moderate response (2×1000 mg = 88% vs. 2×500 mg = 72%; $P < .05$). Other end points, although numerically superior at 48 weeks, did not show any statistically significant difference between the three dosing regimens.

Current Role

Rituximab is generally considered as a cost-effective biologic option in RA patients, particularly if seropositive, with inadequate responses to TNF inhibitors. Recent advances in the understanding of the pathogenesis of RA emphasize the critical role of B cells in self-sustaining chronic inflammatory processes. Rituximab is a promising addition to the therapeutic armamentarium for the treatment of RA. In current clinical practice, the major use for rituximab in the treatment of RA is confined to the TNF inhibitor–refractory population. Data from a number of clinical trials (IMAGE, MIRROR, SERENE, REFLEX, and DANCER)^{24,27,28,51} suggest that seropositive RA patients (RF and/or anticyclic citrullinated peptide [anti-CCP]) show a higher likelihood of response to B cell–depleting therapy compared with seronegative patients, in particular for improving signs and symptoms and inhibition of radiographic changes. However, it is nevertheless the case in both trials and clinical experience that a proportion of seronegative RA patients

show good clinical responses, although this proportion is less than in the case of seropositive patients. In pooled analyses of data from the MIRROR and SERENE studies, at week 48, odds ratios for seropositive patients versus seronegative patients of achieving ACR20, ACR50, and ACR70 responses were 2.23 (95% CI, 1.38 to 3.58), 2.72 (95% CI, 1.58 to 4.70), and 3.29 (95% CI, 1.40 to 7.82), respectively.⁵³ These observations generate the hypothesis that other mechanisms may account for lower levels of response in seronegative patients such as antigen presentation, co-stimulation, and cytokine drive, whereas high levels of response to rituximab therapy may be mediated primarily by the suppression of pathogenic antibodies. In contrast to RF, the type I interferon (IFN) signature is associated with a negative response to rituximab therapy in RA patients.⁵⁴

The optimal and most cost-effective dosing regimen for rituximab remains a matter of debate. The phase III SERENE study showed equal clinical efficacy for the 500 mg \times 2 and 1000 mg \times 2 rituximab doses,²⁷ but the phase III MIRROR trial⁵¹ had differences in some outcomes favoring the higher dosage. Methotrexate-naïve patients (not an approved patient population for rituximab) were studied in the IMAGE study with clinical results that were equivalent, but with a radiographic result that favored the higher dosage.²⁸ Thus a summary of the current randomized controlled trial data on rituximab dosing is that 1000 mg \times 2 works well in a clinically meaningful proportion of patients, but not in all. The 500 mg \times 2 rituximab dose achieves broadly similar results in the relevant patient populations overall and has the advantages of lower cost and possibly a lower rate of serious adverse events but perhaps with lower probability of high-impact clinical responses and inhibition of structural damage. On the basis of the DANCER study findings, it is recommended that each cycle of 1000 mg \times 2 rituximab be given in combination with once-weekly methotrexate, usually at doses of at least 15 mg/week, to optimize efficacy. Further, administration of 100 mg intravenous methylprednisolone is recommended before each rituximab infusion to reduce the frequency and severity of infusion reactions.

Rituximab may also have a role in those patients for whom TNF blockade is relatively contraindicated such as those with connective tissue disease overlap syndromes. At present, there are uncertainties about the implications of long-term peripheral B cell depletion and the timing and need for redosing with rituximab in patients who respond. Current research suggests that restoration of peripheral B cell numbers takes about 8 months after depletion treatment, although retreatment may be necessary earlier. Results have been presented for an open-label study to evaluate the response to repeated courses of rituximab in patients with active RA participating in one of several phase II or III studies and to determine the optimal frequency for repeated treatment.⁵⁵ In a series of 155 patients with prior exposure to TNF inhibitors, ACR20, ACR50, and ACR70 scores were 65%, 33%, and 12%, respectively, following the first course; they were 72%, 42%, and 21%, respectively, for the second treatment course, relative to the original baseline. In 82 of these patients who received a third course of rituximab, the median interval between first and second courses was similar to that between second and third courses: 30 to 31 weeks.⁵⁵

Further studies are necessary to identify the optimal regimens for maintenance therapy that will provide efficacy and limit toxicity.⁵⁶ Development of biomarkers informative of management decisions that would optimize response is a highly desirable goal, but as yet none are in routine use. The magnitude of clinical response appears to be related to the completeness of peripheral B cell depletion. This holds true whether the lower 500 mg \times 2 dose schedule or higher 1000 mg \times 2 schedule is administered. By means of sensitive measurements permitting detection of low numbers of pre-plasma B cells in the circulation, a recent study reported that RA patients whose disease did not respond to an initial cycle of rituximab have higher circulating preplasma cell numbers at baseline and incomplete depletion. Furthermore, an additional cycle of rituximab administered before total B cell repopulation enhances B cell depletion and clinical responses.⁵⁷

Although the available safety data for rituximab in RA are reassuring, they need to be interpreted with caution until larger numbers have been treated and long-term safety and retreatment data become available. Further, there is a substantial body of safety data for rituximab in the treatment of non-Hodgkin's lymphoma, with similarly low infection rates reported. In oncology, some of the associated adverse events are related to circulating tumor loads. Overall, this is reassuring with regard to the RA population, although close monitoring of immunocompetence and for the possibility of rare opportunistic infections is advisable.

Future Directions and Other Approaches to B Cell-Targeted Therapy

Rituximab is currently indicated for the treatment of patients with moderate to severe RA who show no response, experience a loss of response with time, or have adverse effects to anti-TNF alpha agents.⁵⁸ The findings of recently reported studies indicate that rituximab is also efficacious in a proportion of both treatment-naïve and methotrexate patients with RA, particularly if seropositive.^{27,28} Therefore in the face of competitive health economic data compared with TNF inhibitors, there has been interest in its potential as a first-line biologic. However, questions remain about the safety of repeated treatment cycles, although encouraging data are emerging. Although the U.S. Food and Drug Administration (FDA) has received reports of patients who developed fatal PML following rituximab treatment for SLE and RA, this appears to be rare. A key issue determining the future place of B cell depletion therapy will be defining the most effective strategy in early stages of RA to induce a remission and potentially even biologic-free remission, whether this can be achieved safely and effectively with rituximab, and whether any biomarkers can be developed that reliably inform biologic treatment strategy on an individual patient basis.

Clinical trials and safety data for other antibodies targeting CD20 such as ocrelizumab, a humanized version of rituximab, and HuMax-CD20/ofatumumab, a fully human anti-CD20, have also been reported. In phase I/II trials in RA, ocrelizumab, in combination with methotrexate, was found to be safe and effective at doses comprising two infusions of 200 mg or higher given 2 weeks apart.⁵⁹ Researchers

studied two ocrelizumab dose levels in three phase III RA studies across various patient populations and have yet to fully report findings. However, in spring 2010 a decision was announced to discontinue development of ocrelizumab for the RA indication after a detailed analysis of the efficacy and safety data from the RA program found that the overall benefit-to-risk profile of ocrelizumab was not favorable taking into account other currently available treatment options. This decision was based on an infection-related safety signal that included serious infections, some of which were fatal, and opportunistic infections.

Ofatumumab is a human IgG1 κ lytic monoclonal antibody with specificity for human CD20 antigen. It recognizes a unique membrane-proximal epitope on the human CD20 molecule, distinct from the epitope recognized by rituximab and ocrelizumab.⁶⁰ The membrane proximity of this epitope is likely to account for the high efficiency of B cell killing observed with ofatumumab in both in vitro and in vivo preclinical studies. A phase I/II study of ofatumumab, administered as two intravenous infusions of 300, 700, or 1000 mg 2 weeks apart, in active RA patients with an inadequate response to DMARDs, demonstrated significant clinical benefit and reasonable tolerability (improved after implementation of premedication) at all doses investigated when compared with placebo, with the 700-mg dose considered to be optimal.⁶⁰ Despite these positive results in RA studies, in autumn 2010 Genmab and GlaxoSmithKline announced their intention to stop further work on ofatumumab by intravenous delivery in autoimmune conditions and to focus on a subcutaneous delivery program. Plans for a study in multiple sclerosis are under way, but further development in RA remains under review, although this situation has not been prompted by the observation of unexpected opportunist infections, as was the case for ocrelizumab.

Many other approaches to B cell–targeted therapy are in clinical testing, although it is unlikely that any of these will significantly affect the rituximab niche in the near future. Alternative strategies to target the B cell compartment include the use of antibodies BlyS. Belimumab, or LymphoStat-B, is a human anti-BLyS monoclonal antibody recently investigated in clinical trials for the treatment of RA and other rheumatic indications. An alternative approach to BLyS inhibition that is still in the early stages of clinical development is to block signaling through BLyS receptors using a soluble receptor such as transmembrane activator and calcium modulator and cyclophilin ligand interactor immunoglobulin. Preliminary results of a phase II double-blind, placebo-controlled study of belimumab in 283 active RA patients have been presented.⁶¹ Patients were randomized to receive intravenous belimumab at a dose of 1, 4, or 10 mg/kg or placebo infusions on days 0, 14, and 28, then every 28 days through 24 weeks. The ACR20 response at week 24 in the combined belimumab groups was 29%, compared with 16% in the placebo group; no dose response was observed. The antibody was well tolerated. These preliminary findings with a functional inhibitor of B cells are surprising, given the effectiveness of rituximab; however, it may simply represent a pharmacokinetic problem indicating that the dose of belimumab was too low. The benefit-to-risk ratio of belimumab has come under close scrutiny by the FDA, and it seems unlikely that it will progress in clinical development with RA as an indication.

Rituximab in Other Rheumatic Conditions

KEY POINT

Rituximab has demonstrated benefits in studies of RA and ANCA-associated vasculitis. Clinical trials in SLE have not shown clinical benefit.

Rituximab has also been used in a number of other rheumatic diseases.¹¹ Theoretic considerations and preliminary data suggested that B cell depletion using rituximab might have efficacy for immune thrombocytopenia, antineutrophil cytoplasmic antibody–associated vasculitis, and SLE. The rationale for the use of rituximab in the treatment of patients with ANCA-associated vasculitis is that elimination of CD20 B-cell precursors could lead to transient removal of pathogenic antibodies and remission, assuming that ANCAs are produced by short-lived B lineage cells rather than long-living plasma cells. Furthermore, in ANCA-associated vasculitis, the number of activated, circulating B lymphocytes correlates with disease activity and tissue involvement. Therefore the hypothesis that rituximab might induce disease remission in patients with severe ANCA-associated vasculitis has been tested in a phase II/III multicenter, randomized, double-blind, placebo-controlled trial known by the acronym RAVE (rituximab for ANCA-associated vasculitis). Findings have recently been reported comparing rituximab (375 mg/m² administered intravenously once weekly for 4 weeks) to cyclophosphamide (2 mg/kg per day administered orally).⁶² Sixty-three patients in the rituximab group (64%) reached the primary end point, as compared with 52 patients in the control group (53%), a result that met the criterion for noninferiority ($P < .001$). The rituximab-based regimen was more efficacious than the cyclophosphamide-based regimen for inducing remission of relapsing disease; 34 of 51 patients in the rituximab group (67%) as compared with 21 of 50 patients in the control group (42%) reached the primary end point ($P = .01$). Rituximab was also as effective as cyclophosphamide in the treatment of patients with major renal disease or alveolar hemorrhage. There were no significant differences between the treatment groups with respect to rates of adverse events. Despite these encouraging data, the true positive effect of rituximab in ANCA-associated vasculitis is difficult to determine because of the simultaneous administration of high-dose glucocorticoids, which may contribute to a substantial decrease in ANCA titers and the observed remission rates.

Given the large body of evidence implicating abnormalities in the B cell compartment in SLE, a recent therapeutic focus has been to develop interventions that target the B cell compartment by multiple mechanisms, and rituximab has been studied most extensively. The best evidence in support of using rituximab for the treatment of patients with ANCA-associated vasculitis or SLE comes from clinical experience, retrospective case series, and small prospective uncontrolled studies, mainly in patients with refractory or frequently relapsing disease.^{63,64} However, recently two moderately sized phase III randomized placebo-controlled trials of rituximab for the treatment of moderately active nonrenal SLE (EXPLORER) or class III/IV lupus nephritis (LUNAR) have failed to demonstrate superiority of this B

cell-depleting agent over placebo when added to the standard of care, conventional immunosuppressive therapy. Both trials had a relatively short follow-up period. Preliminary data from LUNAR (A Study to Evaluate the Efficacy and Safety of Rituximab in Subjects with ISN/RPS Class III or IV Lupus Nephritis) have been reported.⁶⁵ This multicenter, randomized, double-blind, placebo-controlled trial comprised 144 patients with lupus nephritis (67% of patients had class IV disease) and compared the efficacy and safety of rituximab with placebo. Patients with class III and IV disease and urine protein-to-creatinine ratio greater than 1 were randomly assigned to receive either 1000 mg rituximab or placebo on days 1, 15, 168, and 182, in conjunction with mycophenolate mofetil and corticosteroids. No significant differences were observed in complete or partial renal response or clinical benefit to therapy at week 52, although rituximab administration was associated with significantly reduced titers of antibodies to double-stranded DNA and increased levels of C3 complement component. Serious adverse events such as infection were similar between the two patient groups.

The EXPLORER (A Study to Evaluate the Efficacy and Safety of Rituximab in Patients with Severe Systemic Lupus Erythematosus) trial randomly assigned patients with SLE with moderate to severe disease activity despite treatment with immunosuppressives and corticosteroids to receive either placebo ($n = 88$) or rituximab infusions ($n = 127$).⁶⁶ Patients with active glomerulonephritis were excluded. The British Isles Lupus Assessment Group Index was used to score treatment response four times per week for 52 weeks after the first infusion. Responses were recorded in 66% of patients in the placebo group, and 75.1% of patients were treated with rituximab. The time to a first moderate or severe flare did not differ between groups, but a trend for a prolonged time to first “a” score flare in the rituximab group was observed. Annual rates of severe and moderate disease activity flares were similar, but the mean annual rate of “a” score flares was significantly lower in the rituximab group than in the placebo group (0.86 vs. 1.41). The numbers of adverse events and overall infections were comparable between groups at 78 weeks, although serious infections were more numerous in the placebo group.

Why the LUNAR and EXPLORER studies failed to prove superiority of rituximab to placebo in patients with SLE is unclear, although design flaws seem likely. Overuse of concomitant steroids and continued immunosuppressive treatment could help mask the possible benefits of rituximab. Moreover, consensus on the optimal dose and administration regimen of rituximab in patients with SLE and adjustments for the organ or system involved is lacking. EXPLORER included patients with very active disease treated aggressively with moderate-to-high-dose glucocorticoids, which made the short-term detection of treatment benefits difficult.⁶⁷ Another potential shortcoming for lupus clinical studies in general, including EXPLORER and LUNAR, is that the length of follow-up may have been too short to demonstrate separation between the different treatments. The unexpected failure to show overall clinical benefit of rituximab in SLE trials may also reflect the inadequacy of the clinical outcome instruments employed. This is less likely to be relevant in the LUNAR nephritis study, for which the outcome measurements were more

unequivocal. It is of note that in both the EXPLORER and LUNAR studies, outcomes appeared to be more favorable in African American and Hispanic patients.⁶⁸

Rituximab has also been used in primary Sjögren’s syndrome; granulomatosis with polyangiitis (GPA) (formerly Wegener’s granulomatosis); hepatitis C–associated cryoglobulinemia; antineutrophilic cytoplasmic antibody–associated vasculitides other than GPA such as polyarteritis nodosa, dermatomyositis, and polymyositis⁶⁹; antiphospholipid syndrome; and scleroderma.⁷⁰

TARGETING CO-STIMULATORY MOLECULES

KEY POINTS

Activated T cells are implicated in the pathogenesis of RA and co-stimulation is essential in induction of adaptive immune responses.

Abatacept is a fully human fusion protein comprising the extracellular portion of CTLA-4 and IgG-1 Fc.

Abatacept is a second-line biologic drug that can be used when conventional synthetic DMARDs and/or other biologic drugs have failed to control inflammatory arthritis.

The reported risk of serious infections is no higher with abatacept compared to other biologic drugs.

Abatacept is not associated with cancer risk in clinical reports to date. Larger study groups and long-term study will further clarify this.

Abatacept has acceptable safety across the spectrum of RA-patient populations.

It is administered as a 30-minute intravenous infusion that is usually achieved without complications. Subcutaneous administration is equally effective and is now approved for use in the United States.

Abatacept is generally considered as a biologic option in RA patients with inadequate responses to TNF inhibitors, although recent evidence suggests that the benefit-to-risk profile of abatacept may be most optimal when introduced earlier in the treatment paradigm.

Clinical efficacy of abatacept in RA validates the importance of co-stimulation in the pathogenesis.

Co-stimulation inhibition modulates production of a number of proinflammatory cytokines.

Abatacept has clinical use for RA and polyarticular juvenile idiopathic arthritis.

Clinical trials on abatacept in psoriatic arthritis have shown benefit.

Co-stimulation is an essential step in the induction of adaptive immune responses. Although the role of T cells in the perpetuation of RA has been debated and remains poorly understood, it has long been believed that T cell activation is a key event in the pathogenesis. Successful T cell activation requires multiple signals. One signal is provided by presentation of an antigen bound to cell surface major histocompatibility complex (MHC) molecules on

Figure 64-5 Interactions between antigen-presenting cells and T cells. Successful T cell activation requires multiple signals. One signal is provided by the presentation of an antigen bound to cell surface major histocompatibility complex (MHC) molecules on antigen-presenting cells to a specific T cell receptor (TCR). In the absence of further signals, T cells become unresponsive and may ultimately be eliminated through apoptosis. An important co-stimulatory signal is provided by an interaction between members of the B7 family (either CD80 or CD86) on antigen-presenting cells and CD28 on T cells. After activation, T cells express CTLA-4, which interferes with the B7-CD28 interaction and helps return the cells to the quiescent state.

antigen-presenting cells to a specific T cell receptor. In the absence of further signals, T cells become unresponsive and may ultimately be eliminated through apoptosis. An important co-stimulatory signal is provided by an interaction between members of the B7 family (either CD80 or CD86) on antigen-presenting cells and CD28 on T cells (Figure 64-5). Other key interactions between antigen-presenting cells and T cells are mediated by the binding of ICAM-1 to lymphocyte function-associated antigen 1 (LFA-1), CD40 to CD40 ligand, LFA-3 to CD2, and so on. After activation, T cells express cytotoxic T lymphocyte antigen-4 (CTLA-4), which interferes with the B7-CD28 interaction and helps return the cells to the quiescent state.

Abatacept in Rheumatoid Arthritis

Abatacept is a novel, fully human fusion protein comprising the extracellular portion of CTLA-4 and the Fc fragment of a human IgG-1 (CTLA4Ig). In December 2005, abatacept (Orencia) became the first co-stimulatory blocker to be approved by the FDA for the treatment of patients with RA who have had an inadequate response to other drugs. Abatacept binds to CD80 and CD86 on antigen-presenting

cells, thus preventing these molecules from binding their ligand, CD28, on T cells, with the consequent inhibition of optimal T cell activation. In vitro, abatacept decreases T cell proliferation and inhibits the production of TNF, IFN- γ , and interleukin (IL)-2. CTLA4Ig showed promising activity in rodent collagen-induced arthritis models, prompting its evaluation in several clinical trials in patients with RA.^{71,72}

Clinical Studies

Abatacept has been evaluated in several double-blind, placebo-controlled trials in a number of clinical scenarios in adults with active RA. These include an inadequate response to conventional DMARDs such as methotrexate or to TNF inhibitors and, more recently, methotrexate-naïve patients in the early phase of disease. In addition, data have been reported in the context of an exploratory phase II study designed to assess the effect of co-stimulation blockade on progression of undifferentiated, early inflammatory arthritis to fulfillment of classification criteria for RA.

An initial 3-month, phase IIa, double-blind, randomized, placebo-controlled pilot study demonstrated the efficacy of B7 blockade in treating the signs and symptoms in patients with active RA despite treatment with at least one conventional DMARD.⁷³ In this pilot study, the effect of one of two different biologic co-stimulatory modulators was compared with that of placebo infusions. The two biologic agents used were CTLA4Ig, which binds approximately fourfold less avidly to CD86 than to CD80, and LEA29Y (belatacept), a second-generation CTLA4Ig with two mutated amino acid residues conferring an increased avidity for CD86 over that of the parent molecule. The proportion of patients achieving ACR20 responses on day 85 was dose dependent, suggesting clinical efficacy for both co-stimulatory blocking molecules.

The findings were confirmed in a multicenter phase IIb study of abatacept plus methotrexate in 339 patients with active RA despite methotrexate treatment.⁷⁴ In this study, patients were randomized to receive infusions of placebo, abatacept 2 mg/kg, or abatacept 10 mg/kg at baseline, 2 weeks, 4 weeks, and then monthly through 6 months. ACR20 responses were achieved in 60%, 41.9%, and 35.3% of patients receiving abatacept 10 mg/kg, abatacept 2 mg/kg, and placebo, respectively. At the more stringent ACR50 response level, the figures were 36.5%, 22.9%, and 11.8% (Table 64-2). Improvements in the individual components of the ACR response criteria were generally greater in the 10 mg/kg group than the 2 mg/kg group. No deaths, malignancies, or opportunistic infections were reported for

Table 64-2 Percentage of Patients Achieving Responses at 24 Weeks in the AIM and ATTAIN Studies

Study	Drug Regimen	ACR20	ACR50	ACR70
Phase IIb AIM ⁷⁴	Abatacept 10 mg/kg plus methotrexate	60	37	17
	Methotrexate	35	12	2
Phase III AIM ⁷⁷	Abatacept 10 mg/kg plus methotrexate	68	40	20
	Methotrexate	40	17	7
Phase III ATTAIN ⁷⁸	Abatacept 10 mg/kg plus methotrexate	50	20	10
	Methotrexate	20	4	1

ACR, American College of Rheumatology; AIM, Abatacept in Inadequate Responders to Methotrexate; ATTAIN, Abatacept Trial in Treatment of Anti-TNF Inadequate Responders.

any patient receiving abatacept during the 6 months of therapy. Patients in the phase IIb study continued on blinded therapy for an additional 6 months, during which time response to therapy was maintained. For patients receiving abatacept 10 mg/kg, the ACR70, ACR50, and ACR20 response rates were 21%, 42%, and 63%, respectively, compared with 8%, 20%, and 36% for patients receiving placebo infusions. Further, at the higher dose, statistically significant improvements in physical function and health-related quality of life were maintained over the 1-year period.⁷⁵ In the phase IIb study, from day 90 onward, there were statistically significant and progressively rising differences in remission rates between the group receiving methotrexate plus abatacept 10 mg/kg and the group assigned to methotrexate and placebo infusions. By 1 year of treatment, 34.8% of abatacept plus methotrexate patients achieved a DAS28 remission (<2.6), in contrast to 10.1% of the methotrexate plus placebo patients ($P < .001$).⁷⁵ Patients completing the double-blind phase over 12 months became eligible to enter a long-term extension phase in which all participants received methotrexate plus abatacept 10 mg/kg. At year 3, abatacept-treated patients experienced greater than 70% improvement in swollen and tender joint counts and approximately 50% improvement in pain and physical function.⁷⁶ Patients who received placebo infusions during the double-blinded phase and then switched to abatacept during the long-term extension rapidly achieved equivalent efficacy to those treated with abatacept throughout.

The findings of two large phase III studies of abatacept in different RA populations were recently reported. A population of methotrexate-refractory patients was studied in the Abatacept in Inadequate Responders to Methotrexate (AIM) trial. This study was designed to further evaluate the safety and clinical efficacy of abatacept plus methotrexate, as well as the effect on radiographic progression.⁷⁷ In the other phase III study, the Abatacept Trial in Treatment of Anti-TNF Inadequate Responders (ATTAIN),⁷⁸ the objective was to determine whether abatacept is a safe and

effective treatment for RA patients who were unresponsive to previous anti-TNF treatment.

In the AIM study, 652 RA patients with an inadequate response to methotrexate were randomly assigned to receive placebo (219 patients) or a fixed dose of abatacept approximating 10 mg/kg (433 patients) on days 1, 15, and 29 and every 4 weeks thereafter for a year. All patients remained on background methotrexate therapy.⁷⁷ Both patient groups exhibited high disease activity at baseline, with a DAS28 of 6.4. Patients receiving abatacept showed greater improvement in all ACR response criteria at 6 and 12 months than did placebo-treated patients (see Table 64-2). In findings similar to the phase IIb study, abatacept plus methotrexate induced DAS28 remission (<2.6) in 14.8% of patients at 6 months and in 23.8% at 12 months, compared with 2.8% and 1.9% of patients receiving methotrexate plus placebo at the corresponding time points ($P < .001$). Physical function significantly improved in 63.7% of the abatacept plus methotrexate group, versus 39.3% of the placebo plus methotrexate group ($P < .001$). Further, patients on the abatacept and methotrexate combination had a slower progression of mean structural damage (1.2 total Sharp score points over 1 year) compared with methotrexate alone (2.3 Sharp score points).⁷⁷ Of interest, when assessed by conventional clinical outcome measures such as EULAR response, the data suggest that a plateau of clinical efficacy is achieved with abatacept between 4 and 6 months of treatment. However, using more stringent measures for analyses, such as time to a low DAS (DAS28 < 3.2) or time to a sustained low DAS, no plateau of efficacy was observed over the first 12 months, suggesting an ongoing recruitment of clinical benefit with abatacept plus methotrexate.⁷⁹

Patients completing the double-blind phase of the AIM study over 12 months became eligible to enter a long-term extension phase in which all participants received methotrexate plus abatacept at a fixed dose approximating 10 mg/kg every 4 weeks (Figure 64-6). Clinically meaningful reductions in disease activity were maintained through 2 years, accompanied by an improved sense of subjective

* \geq swollen joints (66 joint count), ≥ 12 tender joints (68 count) and CRP ≥ 1.0 mg/dL and ≥ 3 months on MTX ≥ 15 mg/week.

well-being assessed by patient-reported outcomes.⁸⁰ Further, inhibition of structural damage to joints was sustained, as evaluated by plain radiography; the effect after 2 years of abatacept was significantly greater than that at 1 year, with minimal radiographic progression observed over the second year of treatment.⁸¹

A third trial in methotrexate-inadequate responders provided the opportunity to evaluate two biologics in a single study. The placebo- and active comparator-controlled ATTEST (abatacept or infliximab vs. placebo, a trial for tolerability, efficacy and safety in treating RA) study, although not powered to detect superiority, provided information on the relative efficacy and safety profiles of abatacept and infliximab versus placebo in the same population.⁸² Patients with an inadequate response to methotrexate were randomized (3:3:2) to abatacept (approved dose, $n = 156$), infliximab (3 mg/week, $n = 165$), or placebo ($n = 110$), with background methotrexate. At month 6, patients in the placebo group were switched to abatacept, and infliximab and abatacept groups continued to year 1, with blinding maintained. The primary end point of this trial, reduction in DAS28 (erythrocyte sedimentation rate [ESR]) at month 6 for abatacept versus placebo, was met, with mean reductions of -2.53 versus -1.48 ($P < .001$), respectively. The proportion of patients achieving low disease activity and DAS28 remission was also greater with abatacept. Improvements in ACR20, ACR50, and ACR70 responses at month 6 were significantly greater versus placebo for both abatacept and infliximab. The onset of ACR20 responses was generally more rapid for infliximab than abatacept, but responses were similar by month 3. By year 1, DAS28 (ESR) reductions of -2.88 and -2.25 were seen for abatacept- and infliximab-treated patients, respectively, and ACR responses were maintained from month 6 with abatacept but not with infliximab treatment.

In the ATTEST phase III study, abatacept therapy was evaluated in 391 patients with active disease receiving

* DMARD/anakinra regimen stable for 28 days.

† Washout = 30 days for etanercept; 60 days for infliximab.

conventional DMARDs or anakinra who failed to respond adequately to at least 3 months of therapy with etanercept, infliximab, or both agents at the approved doses.⁷⁸ Anti-TNF therapy was discontinued at the time of enrollment if it had not been stopped previously. Following a washout period, patients were randomly assigned in a 2:1 ratio to receive either the same fixed dose of abatacept (approximating 10 mg/kg) or placebo (Figure 64-7). Patients receiving abatacept showed significantly greater improvement in all ACR response criteria through 6 months (see Table 64-2) than did placebo-treated patients (ACR20 response, 50.4% vs. 19.5%, $P < .001$; ACR50 response, 20.3% vs. 3.8%, $P < .001$; and ACR70 response, 10.2% vs. 1.5%, $P = .003$) (Figure 64-8). Further, a DAS28 remission was achieved in 10% of patients receiving abatacept, versus only 1% of patients receiving placebo infusions plus DMARDs. ACR20 responses were seen irrespective of whether patients had previously been exposed to etanercept, infliximab, or both anti-TNF therapies without an adequate response. Improvement in physical function was also significantly increased in the abatacept group (47% vs. 23%). The incidence of infection was slightly higher in the abatacept group than in the placebo group, although no specific infection was clearly more frequent, and the intensity of infections was similar in the two groups. There were no significant differences in the number of patients discontinuing treatment as a result of infection or in the incidence of serious infection.

All patients who completed the 6-month double-blind phase of the ATTEST study were eligible to enter a 1-year, long-term extension phase during which all patients

received a once-monthly fixed dose of abatacept in addition to at least one conventional DMARD.⁸³ Of 258 patients randomized to abatacept during the double-blind phase, 223 completed 6 months of treatment and 218 entered the long-term extension. Of these, 168 completed 18 months' treatment. The ACR20 responses observed at the end of the double-blind phase were sustained throughout the 1-year extension phase, with the proportion of patients achieving the more stringent ACR50 and ACR70 responses rising to 35% and 18%, respectively, at 18 months. Further, the proportion of patients meeting DAS28 remission criteria doubled to 22.5% by the end of the extension period. Similarly, among all patients initially treated with abatacept and DMARDs who entered the long-term extension phase, the mean reduction in DAS28 from baseline to the end of the double-blind phase was -1.99 ; by the end of 18 months, the mean reduction from baseline was -2.81 . In the double-blind phase, patients assigned to placebo infusions together with DMARDs had a mean reduction in DAS28 of -0.93 ; at the end of the long-term extension, after crossing over to abatacept infusions, the reduction from baseline was -2.72 .⁸⁴ These data again emphasize the sustained but relatively slow and incremental clinical responses observed following abatacept therapy.

The second trial conducted in TNF-inadequate responders was a Phase IIIb/IV, 6-month, open-label study. The ARRIVE (Abatacept Researched in RA patients with an inadequate anti-TNF response to Validate Effectiveness) trial was the first to assess the safety of abatacept in patients who switched directly from TNF antagonist therapy without undergoing washout, an approach that may be more clinically relevant for everyday practice.⁸⁵ Enrolled patients in this study had high disease activity levels at entry and an inadequate response to up to three TNF antagonists that they could have failed for efficacy, safety, or tolerability reasons. Patients were eligible even if they had a positive purified protein-derivative test result. Abatacept could be administered as monotherapy (for those recruited in the United States only), and patients were not limited to a particular background DMARD. Similar, clinically meaningful improvements were seen in disease activity, physical function, and health-related quality of life, regardless of whether there was a washout period or not. Post hoc analyses revealed that numerically more patients who had previously failed one TNF antagonist achieved DAS28-defined remission and low disease activity than those who had failed two or more TNF inhibitors.

Because T cell activation is believed to be an initiating event in an immunologic cascade observed in RA, costimulation blockade might be predicted to have benefits from an early stage of evolution of the syndrome independently of any driving antigen or antigens. The 2-year abatacept study to gauge remission and joint damage progression in methotrexate-naïve patients with early erosive RA (AGREE) study consisted of a 12-month double-blind period followed by a 12-month open-label period in methotrexate-naïve patients with early RA.⁸⁶ Eligibility included short disease duration, poor prognostic factors including high C-reactive protein (CRP) levels, radiographic evidence of erosions, and seropositivity for RF or anti-CCP2. Patients were randomized 1:1 to receive abatacept plus methotrexate ($n = 256$) or methotrexate

alone ($n = 253$) over the first 12-month period.⁸⁶ From year 1 onwards, all patients received open-label abatacept plus methotrexate. The co-primary end points were 28-joint DAS (DAS28)-defined remission and radiographic joint damage progression at year 1. Significantly more patients treated with abatacept plus MTX achieved DAS28 (CRP)-defined remission and ACR50 and ACR70 responses at year 1, and the difference between treatment arms was significant by month 2. Over 1 year, 27.3% versus 11.9% of abatacept plus methotrexate versus methotrexate alone-treated patients ($P < .001$) achieved a major clinical response (ACR70 maintained for 56 consecutive months).⁸⁶ Significant improvements were also seen in physical function at year 1, for abatacept plus methotrexate over methotrexate alone-treated patients.⁸⁶ Improvements in disease activity and ACR responses were sustained or improved over the second year for patients remaining on abatacept plus methotrexate therapy, with 55.2% achieving remission at year 2.⁸⁷ Changes from baseline to year 1 in the Genant-modified total Sharp score and erosion score were significantly lower for methotrexate-naïve patients randomized to the abatacept plus methotrexate arm.⁸⁶ Furthermore, there was an increasing degree of inhibition of progression in year 2 relative to year 1 for patients originally randomized to abatacept.⁸⁸ For patients originally receiving methotrexate alone, structural damage progression was reduced over year 2 relative to year 1, following the addition of abatacept.⁸⁷ However, overall structural damage progression at year 2 remained greater for these patients compared with patients who received abatacept from baseline.⁸⁷

The potential for early treatment with abatacept to delay the time for progression to fulfillment of classification criteria for RA in patients with anti-CCP2-positive, undifferentiated, early inflammatory arthritis with clinical synovitis of two or more joints was investigated in an exploratory, phase II, 2-year study known by the acronym ADJUST (Abatacept Study to Determine the Effectiveness in Preventing the Development of RA in Patients with Undifferentiated Inflammatory Arthritis).⁸⁹ Following 6 months of double-blind, randomized (1:1) treatment with either abatacept at the approved dose of approximately 10 mg/kg ($n = 28$) or placebo ($n = 28$), abatacept treatment was terminated. The proportion of patients who developed RA according to ACR 1987 criteria or discontinued due to lack of efficacy at year 1 was assessed. When abatacept was stopped after 6 months, 22 and 17 patients treated with abatacept and placebo, respectively, remained in the study inasmuch as they had not fulfilled classification criteria for RA; by year 2, 7 and 4 patients remained in the study. Numerically more placebo than abatacept patients developed RA over 1 year (66.7% vs. 46.2%), although confidence intervals overlapped. Radiographic assessments demonstrated an inhibitory effect on structural damage progression at month 6, which was maintained for 6 months following therapy cessation, with similar trends observed for magnetic resonance imaging (MRI)-assessed osteitis, erosion, and synovitis.⁸⁹ Abatacept treatment was also associated with reductions in anti-CCP2 levels that persisted beyond cessation of active drug. At enrollment, patients had short symptom duration, and although they did not meet ACR 1987 criteria for RA at the point of

recruitment, more than half already had evidence of one or more erosions and were thus likely to have had early RA. The findings must be interpreted in light of this.

Safety Issues

Safety assessments from abatacept clinical trials have in general demonstrated a comparable overall incidence of adverse events and serious adverse events for abatacept and placebo-treated patients. The safety of long-term abatacept treatment is reported to be consistent, with the incidence of overall adverse events and serious adverse events remaining stable up to 7 years.⁹⁰

A safety analysis, which included 4150 patients who were exposed to abatacept, has been undertaken on pooled data from abatacept clinical trials through December 2007. This represents 10,365 patient-years of exposure, with an average exposure period of 2.5 years.⁹⁰ The incidence of serious infections was generally low, although it was higher for abatacept-treated compared with placebo-treated patients over 1 year (serious infections: 3.47 vs. 2.41 events/100 patient-years, respectively). Records of annual incidence rates for serious infections did not appear to show an increase in risk over time. Pneumonia, bronchitis, cellulitis, and urinary tract infections were the most common causes of hospital admission for infections. Opportunistic infections were rarely observed in this pooled cohort including the following events per 100 patients-years of treatment: *Mycobacterium tuberculosis*, 0.06 events; aspergillosis, 0.02; blastomycosis, 0.01; and systemic *candida*, 0.01.⁹⁰ The incidence of malignancies (excluding nonmelanoma skin cancer) during the double-blind treatment periods was reported to be 0.59 events per 100 patient-years for abatacept-treated versus 0.63 events per 100 patient-years for placebo-treated patients. This low incidence rate did not rise with increasing exposure. In particular, for lung cancer and lymphoma, the incidence rate was 0.24 lung cancers and 0.06 lymphomas per 100 patient-years over the double-blind period and 0.16 and 0.07 lymphomas per 100 patient-years, respectively, over the cumulative period. In order to better interpret malignancy risk data, the incidence rates observed in abatacept studies were compared with those documented in five observational cohorts of biologic-naïve RA patients on nonbiologic DMARDs. Standardized incidence rates for the observational cohorts ranged from 0.4 to 1.06, and for abatacept-treated patients the risk of lung cancer did not appear to be increased with standardized incidence rates ranging from 0.65 to 1.84. The lymphoma risk in abatacept-treated patients appeared to be comparable with that in biologic-naïve RA with standardized incidence rates ranging from 0.60 to 1.23.⁹⁰ In the pooled trial data from double treatment periods, autoimmune events were reported in 1.4% of abatacept-treated and 0.8% of placebo-treated patients. Most events were mild or moderate in intensity, and the most frequently reported was psoriasis with rates of 0.53 and 0.56 events per 100 patient-years, over the double-blind and cumulative periods, respectively.

In clinical practice, it is common to use conventional DMARDs in combination regimens on the basis of the belief that there are additive benefits in terms of efficacy without the downside of unacceptable toxicity. Whether

these same principles apply to the use of abatacept was addressed in the ASSURE trial (Abatacept Study of Safety in Use with Other RA Therapies).⁹¹ This multicenter, randomized, double-blind study investigated the safety of adding abatacept or placebo infusions to a background treatment regimen of at least one of the traditional nonbiologic or biologic DMARDs currently approved for RA treatment for at least 3 months. A total of 1456 patients were randomized 2:1 to receive abatacept at a fixed dose approximating 10 mg/kg by weight range or placebo. A number of interesting observations arose from this study. In the group as a whole, the proportion of serious adverse events occurring in each treatment arm was similar: 13% for abatacept and 12% for placebo. The discontinuations rate due to adverse events was 5% in the abatacept group and 4% in the placebo group. As expected on the basis of prior studies, serious infections occurred more frequently in the abatacept group (2.9%) than in the placebo group (1.9%). There were five deaths in the abatacept group and four in the placebo group; all but one death in each group was thought unlikely to be related to the study drug. All the deaths occurred in patients without concomitant biologic background therapy. However, a subanalysis of the data, based on whether patients were receiving biologic or nonbiologic background therapy, revealed that serious adverse events occurred almost twice as frequently in the subgroup receiving abatacept plus another biologic agent (22.3%) as in the other subgroups (12.5%). A particularly important observation in this study was the increased number of serious infections observed when abatacept was combined with other biologic therapies (5.8% vs. 1.6% for the subgroup on background biologic therapy plus placebo infusions). Further, the clinical benefits of abatacept tended to be less in the patients receiving background biologic therapy than in those with a background of nonbiologic DMARDs. There were no reported cases of lymphoma, demyelinating disorders, or tuberculosis.

The ASSURE trial findings mirrored those of a smaller randomized, placebo-controlled, double-blind pilot study. This phase IIb trial investigated the efficacy and safety of the addition of abatacept infusions at 2 mg/kg over 1 year in patients with at least 8 of 66 swollen joints and 10 of 68 tender joints despite at least 3 months of treatment with twice-weekly 25 mg subcutaneous etanercept.⁹² The biologic combination had limited clinical benefit over etanercept and placebo infusions but was associated with an increase in the proportion of patients experiencing serious adverse events (16.5% vs. 2.8%) and serious infections (3.5% vs. 0%). On the basis of these observations, the use of abatacept is not advised in combination with other biologic therapies.

Emerging data concern the comparative efficacy, safety, and kinetics of response for the anti-TNF antibody infliximab and abatacept.⁸² In a 1-year double-blind study, RA patients with an inadequate response to methotrexate (mean baseline DAS28 of 6.8) and no prior anti-TNF therapy were randomized to receive abatacept at a dose approximating 10 mg/kg every 4 weeks (156 patients), infliximab 3 mg/kg every 8 weeks (165 patients), or placebo every 4 weeks (110 patients). Patients randomized to placebo were switched to abatacept after 6 months but were not included in the 1-year analyses. At the end of the first

6 months, the frequency of serious adverse events was 5.1%, 11.5%, and 11.8% for abatacept, infliximab, and placebo, respectively. In the same order, the frequency of acute infusion-related adverse events was 5.1%, 18.2%, and 10%. Over the 1-year period, infections reported as serious adverse events were more frequent with infliximab (8.5%) than with abatacept (1.9%). These included two cases of tuberculosis, both in infliximab-treated patients. When considered in the light of clinical response data discussed earlier, this and other studies emphasize the relatively slow time to peak clinical response with abatacept in comparison with TNF blockade, with increasing efficacy beyond 6 months. They also point to the possibility of a favorable benefit-risk profile over 1 year. It will be critical to see whether these encouraging early safety data are maintained over the longer term.

Of note, the incidence rate of serious infections observed with abatacept is at the lower end of the range reported in RA patients treated with other biologics. In summary, the long-term integrated safety data from up to eight abatacept trials, representing more than 10,000 patient-years of exposure, confirm that, overall, abatacept has a favorable safety profile that is consistent with observations from the short-term experience in all RA populations studied, with no new clinically important safety issues identified with long-term exposure, a conclusion supported by a recent Cochrane Review.⁹³

Current Role

Abatacept may be used as monotherapy or concomitantly with DMARDs other than TNF antagonists. It is not recommended for use concomitantly with IL-1 or TNF antagonists. The encouraging clinical trial data confirm that abatacept, like rituximab, represents a valuable agent in the therapeutic armamentarium for patients with RA who have not responded adequately to TNF blockade. Abatacept has particular advantages among intravenously delivered biologics for RA, which is the formulation in which it is currently available, in that it is well tolerated and quick to administer and infusion-related problems are rare. However, the clinical responses and radiographic benefits observed with abatacept appear to be greater in methotrexate-naïve patients compared with patients who have failed methotrexate or other DMARDs. Furthermore, patients who previously failed methotrexate treatment appear to demonstrate higher clinical responses than patients who have failed TNF antagonists. These considerations based on recent clinical trial data suggest that the most favorable clinical outcomes with abatacept may be achieved if it is used earlier in the treatment paradigm than has generally been the case since it became available for use in the clinic. Other factors that influence thinking in positioning a biologic therapy are that the comparative effects of abatacept, rituximab, and TNF blockade on structural damage are still unknown. It is clear that when clinical responses are unsatisfactory, combination therapy with methotrexate and an anti-TNF agent may confer significant joint protection compared with methotrexate alone. Thus the merits of switching a patient from a TNF inhibitor to abatacept or rituximab on the basis of a clinical response that is incomplete are not yet clear-cut with respect to disease modification. Other factors likely to

inform the future use and relative positioning of biologics in the clinic include additional long-term safety data, comparative cost-effectiveness analyses, and the perceived convenience of intravenous administration. The popularity among patients of the subcutaneous delivery route out of available choices of parenteral delivery has prompted studies to look at effectiveness and safety of subcutaneously delivered abatacept. Preliminary data look encouraging. In a noninferiority trial in 1457 moderate to severely active RA patients on background methotrexate, weekly subcutaneous injection of an investigational formulation of abatacept, following a single intravenous loading dose provided an improvement in disease activity similar to that observed in patients assigned to monthly intravenous administration.⁹⁴ Supporting studies evaluated safety and efficacy when switching patients from intravenous to subcutaneous abatacept therapy. They investigated immunogenicity, safety, and efficacy when withdrawing patients from and reintroducing them to the subcutaneous formulation. Preliminary data report that subcutaneous abatacept appears to be well tolerated after a 3-month interruption in patients with RA. Subsequent reintroduction is not associated with any impairment of efficacy or safety, compared with continuous dosing.⁹⁵

Implications for Understanding the Pathogenesis of Rheumatoid Arthritis

The clinical efficacy of abatacept in a proportion of RA patients implicates co-stimulatory events in disease pathogenesis. However, there are a number of different mechanisms by which abatacept might mediate immunosuppressive effects in RA. In the RA joint, blocking access of CD28 to CD80 or CD86 might be of little importance because memory T cells, which predominate in inflamed synovium, are much less dependent on this pathway.⁹⁶ A more important mechanism of action in the synovium might be the induction of tolerogenic antigen-presenting cells. Binding of CD80 or CD86 on antigen-presenting cells by CTLA4Ig initiates a “reverse signal,” with induction of tryptophan catabolism and inhibition of antigen presentation. Naïve T cells are located predominantly in lymphoid tissue, and blockade of the CD28-CD80/CD86 interaction in lymph nodes may reduce T cell priming and the production of autoreactive T cells. Interestingly, patients with RA are reported to have higher frequencies of CD28-null T cells.⁹⁷ Further, the level of expression of CD28 is significantly reduced on all naïve T cells and memory CD4⁺, CD28⁺ T cells, a phenomenon related to overproduction of TNF.⁹⁸ A likely consequence of low-density cell surface expression of CD28 is that, for these T cells, abatacept can more readily block the interaction with CD80 and CD86.

The clinical and radiographic benefits of abatacept administration in RA illustrate the importance of the co-stimulation pathway in T cell activation and subsequent amplification of the inflammatory cascade including pathways that promote tissue destruction.⁹⁹ The modulatory effect of co-stimulation blockade on the expression of a range of inflammatory genes in synovial tissue has been demonstrated by quantitative polymerase chain reaction studies and evaluation of synovial biopsies in patients with active RA who received abatacept treatment having

previously failed to respond to TNF inhibitors.¹⁰⁰ Furthermore, a small, largely nonsignificant reduction in cellular content was observed in biopsy samples following abatacept treatment, suggesting that co-stimulation inhibition reduces the inflammatory status of the synovium without disrupting cellular homeostasis.

Abatacept in Other Rheumatic Conditions

In addition to the use of abatacept in the established phase of RA, its use in combination with methotrexate is indicated for the treatment of moderate to severe active polyarticular juvenile idiopathic arthritis in pediatric patients 6 years of age and older who have had an insufficient response to other DMARDs including at least one TNF inhibitor. Results from a 12-month multicenter clinical trial did not show therapeutic benefit of abatacept over placebo in patients with non-life-threatening SLE. In particular, abatacept failed to prevent new disease flares in SLE patients tapered from corticosteroids in an analysis where mild, moderate, and severe disease flares were evaluated together. Serious adverse events were higher in the abatacept group (19.8% vs. 6.8%). Although the primary and secondary end points were not met, there were improvements in certain exploratory measures.¹⁰¹ There are ongoing studies in type 1 diabetes and inflammatory bowel disease. Abatacept was also used in a 26-week, phase I, open-label dose-escalation study of psoriasis vulgaris.¹⁰² Sustained improvements of at least 50% in clinical disease activity were reported following four infusions of abatacept in 20 of 43 patients with stable psoriasis vulgaris. Clinical improvement was associated with quantitative reduction in epidermal hyperplasia, which correlated with a quantitative reduction in skin-infiltrating T cells. However, no clear-cut increase in the rate of intralesional T cell apoptosis was identified. It may be that the observed reduction in lesional T cell numbers was due to inhibition of T cell proliferation, T cell recruitment, or apoptosis of antigen-specific T cells at extralesional sites. Altered antibody responses to T cell-dependent neoantigens were observed, but immunologic tolerance to these antigens was not demonstrated. This study illustrates the importance of the CD28-CD152 pathway in the pathogenesis of psoriatic skin disease. The findings of a 6-month, double-blind, placebo-controlled phase II trial in psoriatic arthritis have recently been reported.¹⁰³ The study included 170 adults meeting the Classification Criteria for Psoriatic Arthritis (CASPAR) with active arthritis (≥ 3 swollen joints and ≥ 3 tender joints), active plaque psoriasis (at least one qualifying target lesion ≥ 2 cm in diameter), and a disease duration of at least 3 months. All participants were required to have an inadequate response to DMARDs including, but not limited to, methotrexate or anti-TNF therapies. Those who were either intolerant of, or had inadequate response to, TNF inhibitors discontinued these therapies at screening and, following a washout period of 28 or more days, were assessed for arthritis and psoriasis before randomization. Methotrexate was the only DMARD permitted to be continued at a stable dose during the study (in $\approx 60\%$ of participants). The participants were randomized to receive placebo or abatacept at a dose of 3, 10, or 30/10 mg/kg (two initial doses of 30 mg/kg followed by 10 mg/kg) on days 1, 15, and 29 and then every 28 days. The primary end point

was the ACR20 response at the end of 6 months. Key secondary end points included Investigator's Global Assessment (IGA) of psoriasis (ratings ranging from 1 [clear] to 4 [severe]) and the scores for target lesion (TL; based on the rating of skin erythema, induration, and scaling on a scale of 0 to 4 each), the HAQ-DI, and SF-36 General Health Survey. A total of 19%, 33%, 48%, and 42% of patients achieved an ACR20 with placebo, abatacept 3, 10, and 30/10 mg/kg, respectively. Compared with placebo, improvements were statistically significantly higher for the abatacept 10 mg/kg ($P = .006$) and 30/10 mg/kg ($P = 0.022$) dose groups, but not for 3 mg/kg ($P = .121$). An IGA response (rating of psoriatic lesions as "clear or almost clear") was seen in 21% of the 30/10 mg/kg dose group, 25% of the 10 mg/kg group, and 38% of the 3 mg/kg—the latter was the only one that was statistically significantly different to placebo (26%; no statistical data presented). All doses of abatacept showed improvements in scores on magnetic resonance imaging for joint erosion, osteitis, and synovitis; HAQ; and the SF-36 General Health Survey. These encouraging early findings suggest that abatacept 10 mg/kg may be a treatment option for patients with active psoriatic arthritis previously exposed to DMARDs including anti-TNF therapies. Longer-term follow-up of these patients is ongoing, and further studies are planned.

TARGETING T CELLS

KEY POINTS

A number of approaches to targeting T cells independently from co-stimulation pathways have not shown clear-cut benefit in clinical trials.

Novel approaches to targeting T cells are being tested including T cell vaccination.

Clinical Studies

In the early years of investigating the potential of biologic therapies in RA, T cells were among the first targets to be explored. Data from several different preclinical animal models of inflammatory arthritis suggested a pathogenic role for CD4⁺ T cells in response to various arthritogenic antigens presented in the context of MHC class II molecules.⁹⁶ These observations led to a number of experimental protocols designed to investigate the effect of depleting and non-depleting antibodies directed at CD4, as well as other T cell-associated molecules. Early randomized, placebo-controlled clinical studies exploring the potential of biologic therapies targeting T cells in the treatment of RA have generally had disappointing results. Some anti-T cell agents were not efficacious; other preliminary trials demonstrating some clinical efficacy were terminated owing to adverse events, particularly prolonged and profound T cell depletion.¹⁰⁴ However, the primatized monoclonal anti-CD4 antibody keliximab results in a dose-dependent clinical response when administered once weekly over 4 consecutive weeks, and the clinical response correlates with CD4⁺ T cell coating with keliximab rather than T cell depletion. In two consecutive randomized, double-blind trials with comparable populations, keliximab treatment was

associated with CD4⁺ T cell counts below 250 cells/mm³ in 12% in one study and 47% in the other.¹⁰⁵

Examples of biologic therapies targeting other T cell-associated molecules include Campath-1H, a monoclonal antibody directed against CD52; a monoclonal anti-CD5 antibody linked to ricin toxin; and a fusion protein comprising an IL-2 receptor-binding domain coupled to diphtheria toxin (DAB₄₈₆IL-2 fusion toxin). CD52 is a polypeptide expressed on all lymphocytes. Campath-1H was tested as a treatment for refractory RA in two small trials, and although a single intravenous dose of between 1 and 100 mg resulted in significant CD4⁺ T cell depletion and clinical improvement in more than half of patients, there was poor correlation between biologic action and clinical response.^{106,107} Further, therapy was associated with significant acute toxicity, presumed to reflect a cytokine release syndrome including headache, nausea, and hypotension. Arthritis activity returned over time despite prolonged suppression of peripheral blood CD4⁺ T cell numbers.

CD5 is a transmembrane glycoprotein expressed on 70% of T cells. CD5-1C, a monoclonal antibody linked to ricin, a plant toxin that inhibits protein synthesis, was used to treat RA in a double-blind, placebo-controlled trial.¹⁰⁸ At the doses tested, only modest and transient T cell depletion was observed and there was no clinical benefit.

In a strategy designed to selectively deplete activated T cells expressing IL-2 receptor, DAB₄₈₆IL-2 fusion toxin was given by intravenous infusion in open-label and placebo-controlled studies.^{109,110} Although a small percentage of patients (18%) exhibited clinical responses in the placebo-controlled study, there was a significant incidence of adverse events including nausea, fever, and raised plasma transaminases. Further, nearly all patients developed antibodies against diphtheria toxin.

Other approaches to targeting T cells that have been tested include efforts to directly interfere with the trimolecular complex comprising HLA class II, antigenic peptide, and T cell receptor (TCR) by means of a DR4-DR1 peptide vaccine, T cell receptor Vβ peptide vaccine, collagen, or cartilage glycoprotein 39.¹¹¹ Despite a rationale for these approaches based on promising preclinical animal model data, all have been abandoned because of borderline or absent clinical benefits in human disease.

Future Directions

The importance of immune regulation in maintenance of the healthy state is perhaps best illustrated by the consequences of immune dysregulation, a phenomenon common to a wide range of chronic inflammatory disease phenotypes. Emerging evidence points to the importance of certain CD4⁺ T cell subsets in the negative regulation of the adaptive immune system. Best characterized of these subsets are the so-called naturally occurring CD4⁺CD25⁺ regulatory T cells and IL-10-producing Tr1 cells. Recent advances in the understanding of the molecular basis of CD4⁺CD25⁺ regulatory T cell generation include the observation that the X-linked forkhead-winged helix transcription factor Foxp3 is required for CD4⁺CD25⁺ T cell development and function. Although further progress in understanding the pathophysiologic role of regulatory T cells will require the identification of more specific markers for distinct

regulatory T cell populations, there is already evidence of the feasibility of enhancing regulatory T cell function *in vivo* by either T cell receptor modulation, using antibodies to CD3, or co-stimulatory signals, using a CD28 superagonist.¹¹²

Where a chronic inflammatory disease reflects an antigen-driven process, an attractive goal is to modulate T cell function in such a way as to generate antigen-specific unresponsiveness in the absence of long-term generalized immunosuppression. Some, but not all, studies report a relative deficiency of regulatory T cells in RA.²⁹ Of note, antibodies to CD3 and TNF appear to enhance regulatory T cell function or number in RA patients.¹¹³⁻¹¹⁶ This raises the possibility that combination treatment with anti-CD3 and anti-TNF might be beneficial in more completely restoring immune regulation in RA. In fact, chronic inflammation and overproduction of TNF perturb T cell antigen receptor-dependent signaling,¹¹⁷ suggesting that active inflammation may attenuate tolerogenic signals expected to be induced by a nondepleting anti-CD3 antibody. Thus pretreatment with TNF blockade might restore tolerogenic signals transduced by the T cell receptor in response to drugs such as anti-CD3. Although the use of anti-CD3 in the clinic has been limited by the occurrence of drug-induced cytokine release syndrome,¹¹⁸ the effects can be modulated by anti-TNF agents, as demonstrated in patients treated for acute allograft rejection.¹¹⁹ Such a combination therapy approach has yet to be tested in RA.

A potentially beneficial immunomodulatory response has been demonstrated in a small open pilot study by vaccinating 16 RA patients with expanded, activated, and irradiated autologous synovial fluid T cells.¹²⁰ Vaccination was associated with expansion of CD4⁺ and CD8⁺ T cells, many of which expressed the Vβ2 T cell receptor chain. Some were anti-idiotypic, responding specifically to vaccine T cells with the production of IL-10 (CD4⁺ cells) or granzyme B (CD8⁺ cells). A broader regulatory response, however, was directed toward activated T cells in general, specifically against peptides derived from the IL-2 receptor α-chain. This broader response may be important to generate in a syndrome such as RA where the precise autoantigen and pathogenic T cell clones are not readily identifiable. This might also explain why earlier attempts at T cell vaccination using TCR-derived peptides have not been pursued.¹¹¹ However, the efficacy of such a T cell vaccination approach needs to be validated in further trials and the safety and durability of response further investigated before the potential feasibility of such an approach to therapy in routine clinical use can be properly assessed.

SUMMARY

KEY POINT

Rituximab and abatacept have both established a role in the pharmacologic management of RA.

Despite recent advances in understanding the optimal use of nonbiologic DMARD therapies and the considerable success of biologic therapies targeting TNF, a substantial proportion of RA patients remains refractory to or intolerant of these therapeutic modalities. The data discussed in

this chapter illustrate that there is a role in clinical practice for newer biologics with specificity for cellular targets. In particular, depletion of B cells with the monoclonal antibody rituximab results in sustained improvement in the signs and symptoms of RA after just two doses (one treatment cycle), with little evidence of drug-related toxicity despite the profound and lasting depletion of B cells. Similarly, inhibition of T cell co-stimulation by abatacept demonstrates clear clinical efficacy within 16 weeks and, in some cases, additional improvement for 1 year or beyond, with acceptable safety. This observation is in marked contrast to the previously observed unfavorable risk-to-benefit ratio associated with a T cell-depleting strategy using Campath-1H. The response of RA patients to this wide spectrum of therapeutic strategies attests to the complexity and heterogeneity of the syndrome and provides further impetus for studies that use these therapies to enhance our understanding of disease pathogenesis.

Although both rituximab and abatacept have been shown to benefit a significant proportion of RA patients whether naïve to DMARDs or DMARD experienced, with either biologic, nonbiologic DMARDs or both, to date, little is known about the comparative effects of these treatment approaches on symptoms and signs of disease or on inhibition of structural damage. Furthermore, despite some pointers to biomarkers that might optimize treatment outcomes with a particular therapeutic approach at the cohort level, such as seropositivity in RA patients treated with rituximab, there are as yet no biomarkers that reliably inform the best choice of therapy on an individual basis. Rituximab and abatacept are a welcome addition to the biologic armamentarium for RA, and both agents may also have a role in the pharmacologic management of rheumatic disorders beyond RA alone. It is anticipated that further clinical research and experience in the use of these biologic therapies will help better inform optimal treatment strategies.

KEY POINTS

Urate-lowering therapy (ULT) is central to the management of hyperuricemia in gout.

The goal of ULT administration in gout is to reduce the frequency of acute flares and prevent progressive joint destruction and tophaceous deposition; this goal can be achieved by lowering and maintaining serum uric acid (UA) below 5 to 6 mg/dL.

Optimal ULT requires careful patient selection with attention to comorbid illness, ongoing education, and effective anti-inflammatory prophylaxis with treatment initiation.

Gout is among the most common forms of inflammatory arthritis, affecting between 1% and 3% of most populations with prevalence rates as high as 6% to 7% in older men.¹ The health burden posed by gout is likely to grow with reports suggesting up to a twofold increase in prevalence in recent decades alone.^{2,3} The rapid growth in gout incidence appears to be largely attributable to a near endemic increase in hyperuricemia. Hyperuricemia is the serum concentration above which uric acid (UA) precipitates into monosodium urate crystals typically defined as serum levels of 6.8 mg/dL or 405 $\mu\text{mol/L}$ or greater, resulting from renal “underexcretion” in most cases ($\approx 80\%$) with the remainder due to “overproduction.” UA is the end-product of purine degradation, and circulating concentrations reflect the complex interactions of dietary purine intake, endogenous production, and elimination.

Treatment of chronic gout is based primarily on the use of urate-lowering therapy (ULT). Available ULTs include (1) xanthine oxidase (XO) inhibitors (allopurinol, febuxostat), (2) uricosurics (probenecid, benzbromarone, sulfapyrazone), and (3) uricases (pegloticase) (Table 65-1). This chapter focuses primarily on the most common rheumatic indication for ULT—treatment of hyperuricemia in gout. Optimal use of ULT in gout, regardless of the specific agent used, requires careful consideration of several factors, as detailed in the following sections.

NONPHARMACOLOGIC TREATMENT OF HYPERURICEMIA

The importance of education and lifestyle advice pertaining to weight loss, select dietary restrictions, and reduced alcohol intake has been emphasized in recent gout management guidelines.⁴ Despite a growing list of dietary factors implicated in hyperuricemia and gout, investigations of the effects of dietary interventions on health outcomes in gout

Antihyperuricemic Agents

TED R. MIKULS

are lacking. Furthermore, evidence suggests that such interventions in isolation yield only modest results and suffer from lack of widespread patient acceptance.⁵ In addition to dietary modifications that include reducing the intake of dietary purines, fructose, beer, and liquor, weight loss represents an important goal for overweight gout patients. Although weight loss may lead to reductions in serum UA,⁶ its impact on serum UA appears to be modest and may be insufficient alone in many gout patients.

Patient Selection and Timing of Treatment Initiation

Consensus indicates that hyperuricemia should be treated in gout patients with recurrent and frequent flares, tophi, and/or radiographic changes consistent with gout.^{4,7} For patients with acute gout, ULT should be initiated only after the acute inflammation has resolved because ULT initiation during a flare can amplify the duration and magnitude of symptoms. Conversely, the development of a gout flare complicating ongoing ULT is not an indication to discontinue or hold ULT. Results from a cost-effectiveness analysis in nontophaceous gout, involving a hypothetical patient cohort, suggest that the institution of allopurinol is cost-effective in patients presenting with two or more acute gout flares within a 1-year period.⁸ Available ULTs are not approved for the treatment of asymptomatic hyperuricemia in the absence of gout.

Duration of Urate-Lowering Therapy

In asymptomatic gout patients successfully treated with prior ULT, withdrawal of therapy often results in an abrupt increase in serum UA, and recurrent attacks occur in approximately one-third of patients within 2 years.⁹ Similarly, reductions from continuous ULT to an “intermittent” regimen in previously stable gout patients lead to significantly higher flare rates,¹⁰ and ULT discontinuation in the setting of tophaceous gout leads to recurrent gout flares in a vast majority and to recurrent tophi in nearly half of patients.¹¹ Taken together, these reports suggest that ULT administration should be unabated and “lifelong” in a majority of gout patients.

Target Serum Urate Goals

Evidence suggests that lowering and sustaining serum UA below 6.0 mg/dL ($<360 \mu\text{mol/L}$), a treatment goal advocated in recent gout treatment guidelines,⁴ leads to improved long-term outcomes in gout. ULT reduces the long-term risk of recurrent flare by approximately 60% for each 1 mg/dL

Table 65-1 Dosing and Safety Information for Currently Available Urate-Lowering Therapies in the Management of Gout

Xanthine Oxidase Inhibitors					Primary Site of Metabolism/ Elimination	Adverse Effects	Contraindications (C)/Drug Interactions (DI)
Allopurinol	100-800 mg	Orally daily	1-2 hr (half-life of active metabolite oxypurinol, 15-30 hr)	Orally twice daily	Met: hepatic xanthine oxidase (into oxypurinol) Elim: renal (renal dosing may be required)	Common: gout flare, skin rash, nausea, diarrhea, LFT abnormalities Rare: allopurinol hypersensitivity syndrome (AHS) (more common in HLA-B*5801 +), cytopenias Common: gout flare, skin rash, nausea, arthralgias, LFT abnormalities Rare: cardiovascular events (unclear association), cytopenias	C: concomitant azathioprine, 6-MP, theophylline, prior hypersensitivity DI: azathioprine, 6-MP, theophylline, ampicillin/amoxicillin, uricosurics, thiazides, cyclosporine, warfarin, ACE inhibitors (possible), Dilantin, cyclophosphamide, vidarabine
Febuxostat	40-120 mg	Orally daily	6-8 hr	Orally daily	Met: hepatic (glucuronyl conjugation and oxidation via cytochrome P450) Elim: hepatic and renal	Common: gout flare, skin rash, nausea, arthralgias, LFT abnormalities Rare: cardiovascular events (unclear association), cytopenias	C: concomitant azathioprine, 6-MP, theophylline, prior hypersensitivity, severe hepatic impairment DI: azathioprine, 6-MP, theophylline
Adverse effects, contraindications, drug interactions similar for available uricosurics—grouped together below.							
Probenecid	500-2000 mg	Orally twice daily	3-8 hr (500 mg), 6-12 hr (larger doses)	Orally twice daily	Met: hepatic (hydroxylation) Elim: hepatic and renal	Common: gout flare, nephrolithiasis, rash, flushing, nausea, loss of appetite Rare: cytopenias, nephrotic syndrome, anaphylaxis, back pain (rare reports of hepatotoxicity with benzbromarone)	C: prior hypersensitivity, nephrolithiasis, UA overexcretion, concomitantly with other cancer therapies, known blood dyscrasias, active peptic ulcer disease; sulfipyrazone should be avoided in patients with phenylbutazone/pyrazole allergy DI (more extensive for probenecid/sulfipyrazone than for benzbromarone): warfarin, allopurinol, NSAIDs, salicylates, penicillins, cephalosporins, fluoroquinolones, imipenem, rifampin, nitrofurantoin, sulfonamides, heparin, dapsone, acyclovir, ganciclovir, zidovudine, alcohol, diazoxide, mecamlamine, pyrazinamide, antineoplastic agents, clofibrate, dyphylline, diuretics, benzodiazepines, methotrexate, riboflavin, thiopental
Sulfipyrazone	200-800 mg	Orally twice daily	3-12 hr	Orally twice daily	Met: hepatic (CYP2C9) Elim: hepatic and renal		
Benzbromarone	50-200 mg	Orally daily	3 hr (half-life of active metabolite 6-hydroxybenzbromarone ≈30 hr)	Orally daily	Met: hepatic (CYP2C9) Elim: hepatic and renal		
Uricases							
Pegloticase	8 mg*	IV every 2 weeks	Highly variable (days to weeks)	IV every 2 weeks	Not well defined	Common: gout flare, allergic reactions, anaphylaxis (≈7%), infusion reactions (urticaria, dyspnea, chest discomfort, pruritus) Rare: CHF exacerbation (unclear association)	C: allergic reactions to medication or loss of effect (serum UA >6.0 mg/dL indicates development of anti-pegloticase antibody) DI: other PEGylated agents (possible)

*Predosing with fexofenadine 60 mg, acetaminophen 1000 mg, and hydrocortisone 200 mg IV on the day of the infusion.

ACE, angiotensin-converting enzyme; CHF, congestive heart failure; Elim, elimination; IV, intravenously; LFT, liver function testing; Met, metabolism; MP, mercaptopurine; NSAIDs, nonsteroidal anti-inflammatory drugs; UA, uric acid.

decrease in serum urate.¹² Additional evidence suggests that reaching and maintaining serum UA concentrations below 6.0 mg/dL is important for depletion of total body urate stores,¹³ with recognition that lower treatment thresholds (<5.0 mg/dL or <300 μ mol/L) have been advocated by some.¹⁴ It is important to recognize that these target goals often fall well below the upper limit of normal for UA in clinical laboratories that define ranges based on population-based distributions.

Anti-inflammatory Prophylaxis with Urate-Lowering Therapy

Rebound gout is the most common adverse effect with ULT regardless of the agent used, rendering anti-inflammatory prophylaxis a key component of successful gout treatment. Gout flares complicating ULT are thought to be due to reduced serum UA concentrations that result in mobilization of urate from tissue deposits. In fact, the frequency of treatment-related gout flares appears to be greater with more rapid and potent urate-lowering interventions.¹⁵ Both colchicine and naproxen are effective in reducing gout flares during ULT initiation (this is covered in greater detail in Chapter 95).¹⁶⁻¹⁸ Results from Borstad and associates¹⁷ suggest that anti-inflammatory prophylaxis with low-dose oral colchicine (0.6 mg twice daily) protects against rebound gout flares and may need to be continued for at least 6 months following ULT initiation. Although frequently used in gout flare prevention, the efficacy of other anti-inflammatory agents in this setting, including low-dose glucocorticoids and alternative nonsteroidal anti-inflammatory drugs (NSAIDs), has not been defined. Under active investigation for the treatment of acute gout, interleukin-1 inhibition may also represent an alternative means of prophylaxis with ULT initiation.

XANTHINE OXIDASE INHIBITION

Allopurinol

KEY POINTS

Advantages of allopurinol over the most commonly used uricosurics include once-daily dosing, effectiveness in both “underexcretors” and “overproducers,” and potential effectiveness in patients with renal insufficiency.

Allopurinol hypersensitivity syndrome (AHS) is a relatively uncommon albeit potentially serious adverse event associated with its use.

Allopurinol doses greater than 300 mg/day are frequently required to achieve target serum UA goals; evidence and consensus-based gout treatment guidelines recommend the initial use of low-dose allopurinol (≤ 100 mg/day) with gradual increases in dosing to achieve target serum uric acid (UA) goals.

Available for more than 40 years, allopurinol accounts for a vast majority of ULT prescriptions.¹ In addition to its established track record in gout care, allopurinol offers several potential advantages: (1) relatively low cost, (2)

once-daily oral administration in most cases, (3) effectiveness in patients who “underexcrete” and in those who “overproduce” UA, (4) a favorable safety profile, and (5) potential effectiveness in patients with renal impairment. Allopurinol treatment results in significant declines in serum UA,¹⁸⁻²⁰ decreased gout flare rates,¹⁸⁻²⁶ and declines in tophus area.¹⁹

Role in Rheumatic Disease and Indications

Approved indications for allopurinol include (1) treatment of hyperuricemia in gout, (2) management of malignancy (most often leukemia or lymphoma) in patients undergoing cancer treatment that results in marked increases in serum/urinary UA (allopurinol is stopped once UA overproduction is absent), and (3) management of calcium oxalate-associated nephrolithiasis with daily urinary UA excretion greater than 800 mg/day in men and greater than 700 mg/day in women. Although not approved for the treatment of asymptomatic hyperuricemia in the absence of gout, evidence suggests that allopurinol use may lead to other health benefits. Hyperuricemia is independently associated with cardiovascular morbidity and mortality,²⁷⁻³⁰ giving rise to speculation that ULT could be cardioprotective.³¹ In a placebo-controlled study of pediatric essential hypertension, allopurinol use resulted in significant, albeit modest, declines in blood pressure.³² XO inhibition via allopurinol also has been shown to improve endothelial function, improving measures of local and systemic blood flow,³³ and has been associated with improvement in renal function in at-risk populations.^{34,35}

Chemical Structure and Mechanism of Action

An antimetabolite in simple organisms, allopurinol inhibits XO, a key enzyme in purine catabolism, but does not inhibit the biosynthesis of purines in humans (Figures 65-1 and 65-2).

Pharmacology

Pharmacologic characteristics of the ULTs are summarized in Table 65-1. Allopurinol is approximately 90% absorbed from the gastrointestinal (GI) tract and is metabolized into oxypurinol, its active metabolite. Peak serum concentrations for allopurinol and oxypurinol are achieved within approximately 1 to 2 hours and 4 to 5 hours, respectively. The plasma half-life of allopurinol is relatively brief (1 to 2 hours), although the half-life of oxypurinol is substantially longer (≈ 15 hours or longer), allowing for once-daily dosing. Allopurinol is eliminated primarily via glomerular filtration, while oxypurinol undergoes some degree of renal tubular reabsorption. With renal mechanisms primarily responsible for drug elimination, the plasma half-life of allopurinol and, to a greater degree, oxypurinol is increased with renal injury.

Dose and Drug Administration

Allopurinol is available as 100-mg and 300-mg pills for once-daily oral administration (see Table 65-1), with recognition that split dosing has been advocated for daily

Figure 65-1 Endogenous synthesis and elimination of uric acid (UA). UA is the end-product of purine degradation in humans. Xanthine oxidase, which converts hypoxanthine to xanthine and xanthine to UA, is a rate-limiting enzyme in this process and is targeted by select urate-lowering therapies in gout treatment, including allopurinol and febuxostat. Although humans do not express a functional form of uricase, other mammalian species are able to catalyze the conversion of UA into allantoin, which is far more soluble. Recombinant forms of uricase, including pegloticase, have been developed for use in patients with gout in whom treatment has failed. UA in humans is eliminated primarily in the kidneys. Renal excretion of UA is enhanced through uricosuric administration.

doses of 600 mg or greater. Used also in the treatment or prevention of tumor lysis syndrome, allopurinol is available for intravenous administration. Approved at daily doses as high as 800 mg, allopurinol is rarely given at doses exceeding 300 mg/day.³⁶ It is well established that only a modest proportion of patients achieve a target serum UA less than 6.0 mg/dL with allopurinol 300 mg/day. Using a target serum UA threshold of less than 5.0 mg/dL, investigators showed that only one-fourth of gout patients achieve this goal with 300 mg of daily allopurinol—a proportion that increased to 78% with a daily dose of 600 mg.³⁷ The limitation of “standard” dose allopurinol has been borne out in recent randomized clinical trials that have compared fixed daily doses of 300 mg to febuxostat in various doses. In those studies, approximately 40%

of allopurinol-treated gout patients achieved a final study urate level of less than 6.0 mg/dL.^{18,19} Recent gout treatment guidelines recommend that allopurinol should be started at low doses (e.g., 100 mg daily) and increased by 100 mg every 2 to 4 weeks as required to achieve a target urate concentration.⁴ Combined data from two studies suggest that each 100-mg increment in allopurinol is associated with an additional decline in serum urate of approximately 1.0 mg/dL.^{38,39} Although no data directly support the “start low and go slow” approach over the “fixed-dose” approach, it has been suggested that the former strategy could reduce the incidence of rebound gout flares and mitigate treatment-related toxicity.⁴

General consensus indicates that *initial* allopurinol dosing should be adjusted for diminished renal function,^{4,7,14}

Figure 65-2 Chemical structures of available xanthine oxidase inhibitors (allopurinol; its active metabolite, oxypurinol; and febuxostat) and uricosurics (probenecid, sulfipyrazone, and benzbromarone).

which prolongs the plasma half-life of oxypurinol. With age-related increases in gout incidence, the issue of renal dosing has added relevance for the elderly with age-associated declines in kidney function. Commonly cited dosing algorithms suggest administering an initial daily dose of 100 mg or less for patients with a glomerular filtration rate (GFR) below 20 mL/min, and even lower doses for those with more severe renal impairment.⁴⁰ Whether existing dosing guidelines preclude the use of incremental dosing beyond these recommended renal thresholds is controversial. Renal dosing guidelines that have been promulgated⁴⁰ are not evidence based and are founded largely on a single retrospective case series showing that patients who developed allopurinol hypersensitivity syndrome (AHS) were more likely to have renal insufficiency. Indeed, many patients with chronic kidney disease (CKD) have developed AHS even with “appropriately” dosed allopurinol.^{41,42} In their review of 120 gout patients receiving allopurinol, more than half (57%) required daily doses above the “renal threshold” recommended by Hande and co-workers⁴⁰—a strategy reported to be well tolerated in a majority of patients.⁴³

Toxicity

AHS, an uncommon but potentially fatal treatment complication, is a febrile illness characterized by the presence of an erythematous desquamating rash (similar to Stevens-Johnson), eosinophilia, and end-organ damage, including hepatitis and renal failure.⁴⁰ It has been estimated that AHS complicates between 0.1% and 0.4% of allopurinol treatment courses, although rates have been estimated to be as low as 1 in 56,000 allopurinol users.⁴⁴ AHS appears to be substantially more common in individuals positive for *HLA-B*5801*. In a small case-control study, all patients who developed AHS were positive for *HLA-B*5801* compared with just 13% of allopurinol-treated patients without AHS.⁴⁵ This risk allele is seen in approximately 2% to 7% of whites, 7% of blacks, and 8% of Asian Indians.⁴⁶ Given the potential severity of AHS, patients should be educated about the remote possibility of this adverse event and cautioned to discontinue allopurinol with development of rash, particularly if this is accompanied by fever or mucocutaneous lesions.

Given the rare occurrence of AHS, allopurinol is generally well tolerated, with estimates suggesting that less than 5% to 10% of those exposed are intolerant to the drug.⁴⁷ Rebound flares are among the most common adverse event accompanying allopurinol and other ULTs—an issue that is most prominent in the early phases of drug initiation and can be mitigated by anti-inflammatory prophylaxis. Isolated maculopapular skin rash can occur outside the context of AHS and is estimated to complicate approximately 1% to 3% of allopurinol treatment courses. Other common adverse events associated with allopurinol use are summarized in Table 65-1. Liver function abnormalities can be seen in approximately 6% to 7% of allopurinol users,²⁰ although rates of severe liver injury appear to be exceedingly rare. The role and recommended frequency for laboratory surveillance in toxicity monitoring have not been well defined.

Fertility, Pregnancy, and Lactation

Although no human studies have investigated its use in pregnancy,⁴⁸ allopurinol is classified as a Pregnancy Category C agent (animal reproduction studies have shown an adverse effect on the fetus without adequate human studies). Both allopurinol and oxypurinol are expressed in breast milk, and because drug effects on the developing infant are largely unknown, it should be administered to a nursing mother with caution.

Drug Interactions and Contraindications

Allopurinol drug interactions have been well characterized. Azathioprine and 6-mercaptopurine (6-MP) are metabolized primarily by XO, hence co-administration of allopurinol results in marked increases in circulating drug levels that can lead to bone marrow suppression.⁴⁹⁻⁵¹ Theophylline is also metabolized by XO; therefore co-administration of this agent with allopurinol can lead to increased theophylline levels and can potentiate toxicity. Co-administration of allopurinol with ampicillin/amoxicillin has been associated with a higher incidence of drug-related rash.⁵² Thiazide diuretics may also reduce the renal excretion of allopurinol and oxypurinol, and it has been suggested that this could potentiate drug-related toxicity.⁵³ Uricosurics increase the renal excretion of oxypurinol, thus offsetting to some degree the urate-lowering effect of allopurinol treatment.⁵⁴ Allopurinol co-administration may increase drug levels of cyclosporine and warfarin, mandating close monitoring of drug levels and bleeding parameters, respectively. Other allopurinol-associated drug interactions are summarized in Table 65-1. Although regimens for desensitization have been described, allopurinol should be avoided in patients with known allergies such as AHS.

Febuxostat

KEY POINTS

Febuxostat is a potent inhibitor of XO with a chemical structure that is distinct from allopurinol.

Febuxostat represents an alternative for patients for whom allopurinol is not effective because of intolerance or lack of efficacy.

Febuxostat, a potent and selective inhibitor of XO, represents the first ULT approved for gout treatment in more than 40 years.

Role in Rheumatic Disease and Indications

Febuxostat is approved for the treatment of hyperuricemia in patients with gout; similar to all other ULTs, febuxostat is not indicated for the treatment of asymptomatic hyperuricemia. Given its unique structure, febuxostat represents an important alternative means of XO inhibition, particularly in gout patients intolerant to allopurinol.⁴⁷ The role of febuxostat in gout management was recently addressed by an international panel, which provided guidance specific to

indications, contraindications, monitoring, and issues requiring future research.⁵⁵

Chemical Structure and Mechanism of Action

In contrast to allopurinol, febuxostat is a nonpurine analogue that reduces serum and urinary urate concentrations through potent and selective XO inhibition (see [Figures 65-1 and 65-2](#)). In contrast to allopurinol, which may inhibit other enzymes involved in purine and pyrimidine synthesis, febuxostat demonstrates significant enzymatic inhibition only for XO at therapeutic concentrations.⁵⁶

Pharmacology

Following oral administration, febuxostat is rapidly absorbed from the GI tract with approximately 50% absorption, reaching peak plasma concentrations within a few hours⁵⁷ with near complete plasma protein binding (see [Table 65-1](#)). Febuxostat displays linear pharmacokinetics that are not time dependent with drug metabolism occurring primarily in the liver through conjugation via uridine diphosphate glucuronosyltransferase (UGT) and oxidation via cytochrome P450 enzymes.⁵⁷ Peak urate-lowering effects with febuxostat generally occur during the first 5 to 7 days of treatment. Drug elimination occurs via both hepatic and renal pathways. Although active metabolites are produced via oxidation, these are present in much lower plasma concentrations.

Dose and Drug Administration

Febuxostat is available in 40-mg (United States), 80-mg (United States and Europe), and 120-mg (Europe) tablets for oral administration, with usual dosing ranging from 40 mg to 120 mg daily (see [Table 65-1](#)). Febuxostat should be initiated at a lower dose (40 mg to 80 mg daily) and increased to higher doses (80 mg to 120 mg daily) if serum UA remains greater than 6.0 mg/dL after 2 weeks. In a phase II study, serum UA less than 6.0 mg/dL was obtained by 56%, 76%, and 94% of patients receiving 40 mg, 80 mg, and 120 mg per day of febuxostat, respectively, compared with 0% in the placebo-treated group.¹⁵ Mean serum UA reductions were greater with higher daily doses, ranging from a 37% reduction in the 40 mg/day group to 59% in the 120 mg/day group. Two subsequent trials lasting 28 weeks ($n = 1067$)¹⁸ and 52 weeks ($n = 762$)¹⁶ compared febuxostat (80 mg to 240 mg per day) with fixed-dose allopurinol (300 mg daily); both trials used the primary outcome of obtaining a serum UA less than 6.0 mg/dL at the last three consecutive monthly observations. The primary endpoint was achieved by 48% to 53%, 62% to 65%, and 69% of gout patients receiving daily doses of 80 mg, 120 mg, and 240 mg, respectively, compared with 21% and 22% of patients receiving fixed-dose allopurinol. Secondary outcomes in the trial by Becker and associates¹⁶ showed a decline in gout flare rates and an approximately 70% to 80% reduction in gout tophus area over follow-up—differences that were not significantly different from those observed with allopurinol. It is noteworthy that several studies of febuxostat^{16,18,20} employed fixed-dose allopurinol as an active comparator. As detailed previously, current gout treatment

guidelines recommend initiating low-dose allopurinol (i.e., 100 mg/day) with escalations in dosing as needed to achieve target urate thresholds.^{4,14} Because optimal allopurinol dosing strategies were not used in these studies, these results likely overestimate the effectiveness of febuxostat relative to optimally dosed allopurinol.

Metabolized primarily in the liver, febuxostat may not require renal dosing.⁵⁸ This receives support from a few small short-term pharmacokinetic studies that included a small number of patients with renal impairment.^{59,60} Only limited data have been obtained from longer-term studies of febuxostat in patients with moderate renal impairment (serum creatinine, ≈ 1.6 to 2.0 mg/dL), and essentially no data are available from patients with more severe renal dysfunction (serum creatinine > 2.0 mg/dL). Available data, albeit limited, suggest that those with mild or moderate renal impairment (estimated creatinine clearance [CrCl] between 30 and 90 mL/min) experience similar efficacy and similar rates of toxicity compared with those with preserved renal function receiving equivalent doses of febuxostat.^{16,20}

Toxicity

Similar to other ULTs, including allopurinol, rebound gout flares are the most common complication of febuxostat administration, underscoring the importance of anti-inflammatory prophylaxis.¹⁵ Other adverse reactions observed with febuxostat are summarized in [Table 65-1](#); adverse effects appear to occur at similar rates as those observed with allopurinol.^{20,57} In initial studies comparing febuxostat with allopurinol, a slightly higher rate of cardiovascular events was observed in patients receiving febuxostat (0.74 events per 100 patient-years; 95% confidence interval [CI], 0.36 to 1.37) compared with those randomized to allopurinol (0.60 events per 100 patient-years; 95% CI, 0.16 to 1.53).⁵⁷ In the large 6-month CONFIRMS trial, investigators found no differences in rates of cardiovascular events between febuxostat (40 mg/day and 80 mg/day) and allopurinol (200 mg/day to 300 mg/day), given the limited power of this study, with only six adjudicated events occurring during follow-up.²⁰ In this study, withdrawal rates due to adverse events were similar across treatment groups: 6.4% for febuxostat 40 mg/day, 8.1% for febuxostat 80 mg/day, and 8.5% for allopurinol.

Owing to its unique structure and select XO inhibition, it has been suggested that febuxostat may represent a rational alternative for gout patients with a history of allopurinol hypersensitivity. Whether febuxostat can be effectively administered to such patients is not clear, given early reports of hypersensitivity in patients taking febuxostat. In a small retrospective study involving 13 gout patients with a history of severe allopurinol-related adverse reactions, 12 were subsequently treated safely with febuxostat (with 10 achieving target serum urate goals).⁶¹ A single patient developed hypersensitivity vasculitis of the skin.

Fertility, Pregnancy, and Lactation

The effects of febuxostat on fertility are not known. Likewise, no studies have examined the use of febuxostat in pregnant women, although results from animal studies have not suggested a significant risk of teratogenicity.⁵⁷ In the

absence of appropriate human studies, febuxostat is labeled as Pregnancy Category C. It is not known whether the drug is excreted in human milk, and febuxostat should be used only with caution in nursing women because its effects on developing infants are unknown.

Drug Interactions and Contraindications

Although formal drug interaction studies have not been performed, febuxostat should be used with caution with drugs that are metabolized by XO (azathioprine, 6-MP, theophylline) (see Table 65-1). Its use should be avoided in patients with prior hypersensitivity to febuxostat. Owing to hepatic metabolism, febuxostat should not be used in patients with moderate to severe liver impairment.⁵⁵

URICOSURIC AGENTS

KEY POINTS

Probenecid, sulfinpyrazone, and benzbromarone are the most common uricosuric agents used in gout treatment worldwide.

Uricosurics are potentially effective in lowering serum urate levels in patients who underexcrete uric acid, the most common pathologic defect leading to hyperuricemia.

Probenecid and sulfinpyrazone have limited efficacy in the context of renal insufficiency.

Uricosurics, which were introduced more than 50 years ago, represent the first class of ULT to be used in gout treatment.⁶² A complex system of renal handling of urate has been proposed that sequentially includes four components⁶³: (1) near complete glomerular filtration, (2) proximal reabsorption, (3) tubular urate secretion occurring more distally, and (4) reabsorption a second time more distally. Available uricosurics diminish the postsecretory reabsorption of UA, therefore promoting its elimination and reducing circulating urate concentrations. Uricosurics address the most common physiologic defect in gout—UA underexcretion. In addition to promoting renal UA excretion, uricosurics may inhibit the tubular secretion of a number of other compounds, including penicillins. Although many agents display uricosuric properties, the most commonly used uricosurics in gout worldwide include probenecid, sulfinpyrazone, and benzbromarone. Probenecid is the most widely used uricosuric in gout treatment. Owing primarily to concerns of treatment-related toxicity, sulfinpyrazone and benzbromarone are less widely available; neither is currently available in the United States.

Although the focus of this section is on primary uricosurics, several medications have been approved for the treatment of nongouty conditions that have been shown to display uricosuric properties. Secondary uricosurics and their indications are summarized in Table 65-2.⁶⁴⁻⁶⁹ Salicylates exert a paradoxical effect on renal urate elimination, with inhibition of active secretion with lower doses (e.g., <1 g/day) and “uricosuric-like” inhibition of UA reabsorption at higher doses (>4 to 5 g/day). Along with salicylates, losartan has perhaps been most closely scrutinized for its hypouricemic properties—an effect that is mediated via

Table 65-2 Agents Not Approved for Gout Treatment That Display Urate-Lowering Properties

Agent	Usual Indication
Losartan	Hypertension, congestive heart failure
Fenofibrate	Hyperlipidemia, hypertriglyceridemia
Atorvastatin	Hyperlipidemia
Rosuvastatin	Hyperlipidemia
Guaifenesin	Upper respiratory airway congestion
Leflunomide	Rheumatoid arthritis
Salicylates (high-dose)	Analgesia, fever, anti-inflammatory

inhibition of URAT1 and appears to be specific to this angiotensin receptor blocker (ARB).⁶⁵ The magnitude of UA lowering that can be achieved with these secondary hypouricemic agents is modest. Losartan used at an antihypertensive dose (50 mg/day) resulted in a mean approximately 9% decline in serum UA concentrations.⁶⁵ It is important to recognize that the urate-lowering effect of losartan appears to be negated when co-administered with hydrochlorothiazide,⁷⁰ a combination used in hypertension treatment.

Role in Rheumatic Disease and Indications

Probenecid, sulfinpyrazone, and benzbromarone are used to treat hyperuricemia associated with gout and are indicated in gout patients who underexcrete UA (24-hour urine UA, <700 mg). Probenecid is also approved as an adjuvant to penicillin therapy, increasing plasma concentrations and prolonging the terminal half-life of penicillin and other penicillin derivatives. Although potentially effective for most gout patients, uricosurics are much less commonly used than allopurinol. In a population-based study from the United Kingdom, uricosuric therapy accounted for less than 5% of all ULT prescriptions.¹

Chemical Structure and Mechanism of Action

The chemical structures of probenecid, sulfinpyrazone, and benzbromarone are shown in Figure 65-2. Uricosurics work primarily through inhibition of the renal tubular urate-anion exchanger, URAT1 (SLC22A12), in addition to GLUT9 (SLC2A9). Thus, uricosurics reduce UA reabsorption, promote renal elimination, and decrease circulating urate concentrations (Figure 65-3).⁷¹⁻⁷⁵

Pharmacology

Administered orally, the uricosurics undergo GI absorption and are extensively protein bound in the serum. The half-lives of probenecid⁷⁶ and sulfinpyrazone⁷⁷ are relatively brief, ranging from approximately 3 to 12 hours (see Table 65-1). Although benzbromarone also has a relatively short half-life of approximately 3 hours, its active metabolite 6-hydroxybenzbromarone has a much longer half-life, allowing for effective once-daily administration.⁷⁸ Elimination of the uricosurics occurs primarily via hepatic metabolism followed by variable excretion of metabolites in the urine, bile, and/or feces. The metabolism of probenecid is limited to side-chain hydroxylation, N-depropylation, and glucuronic conjugation of its carboxyl group.⁷⁹⁻⁸¹

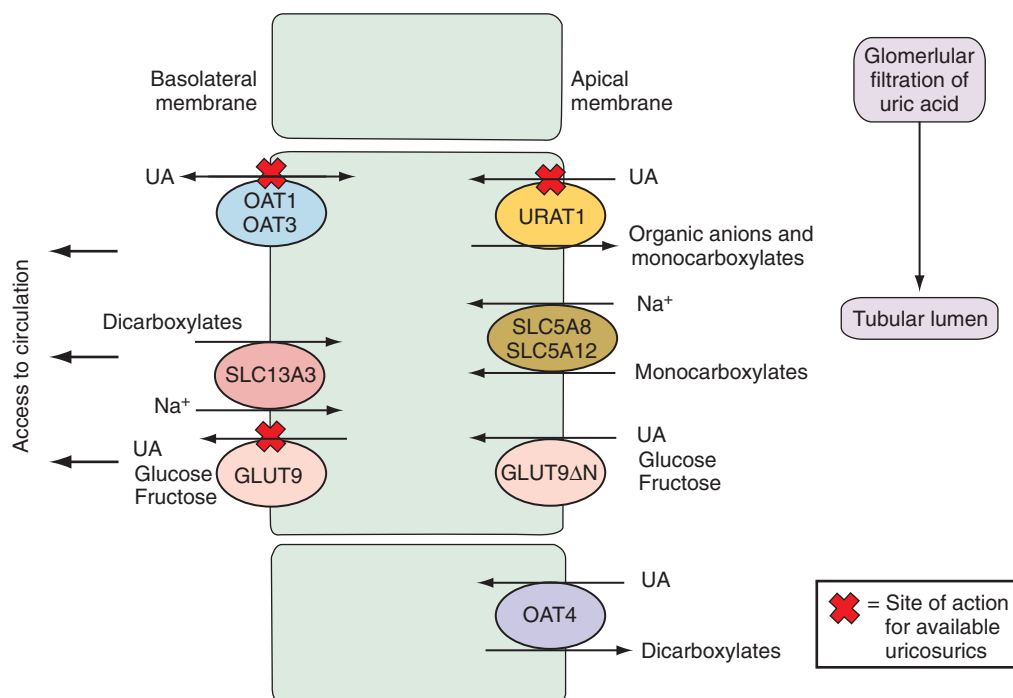

Figure 65-3 Renal handling of uric acid (UA) and sites of action for available uricosurics, including probenecid, sulfapyrazone, and benzbromarone, in the proximal renal tubule. Serum UA undergoes near complete glomerular filtration. UA reabsorption is then mediated primarily by URAT1 and GLUT9 transporters in the proximal tubule, and reabsorption is inhibited by available uricosurics. Tubular reabsorption of UA requires sodium (Na^+)-dependent loading of monocarboxylates and dicarboxylates, which are subsequently exchanged with UA via URAT1 (monocarboxylates) and organic anion transporter (OAT)-4 (dicarboxylates). Monocarboxylates include lactate, pyruvate, acetoacetate, hydroxybutyrate, and acetate. Dicarboxylic acids include oxalic acid, malonic acid, and succinic acid among others. In addition to facilitating UA exchange, GLUT9 mediates the reabsorption of glucose and fructose. RDEA 594 is an investigational uricosuric that appears to inhibit URAT1 specifically; tranilast (also an investigational agent) inhibits both URAT1 and GLUT9 transporters. (Modified with permission from Dalbeth N, Merriman T: *Crystal ball gazing: new therapeutic targets for hyperuricaemia and gout*, *Rheumatology* 48:222–226, 2009.)

Both sulfapyrazone and benzbromarone are metabolized via cytochrome P450 (CYP), with CYP2C9 representing a principal mediator.^{82,83} Warfarin is also metabolized primarily via CYP2C9, explaining its drug-drug interactions with both sulfapyrazone and benzbromarone.

Dose and Drug Administration

Usual probenecid dosing is 500 to 2000 mg daily in divided doses. Probenecid (500 mg) is also formulated with colchicine (0.5 mg) as a combination tablet (colbenemid). In a 12-week randomized study involving patients with preserved renal function, probenecid 1500 mg/day was associated with a 32% reduction in plasma urate concentration,⁸⁴ and older studies have documented other qualitative benefits of therapy, including softening of tophi, functional improvement, and improved pain symptoms.^{25,85} Sulfapyrazone is given in divided doses at an initial daily dose of 200 to 400 mg, increasing to 800 mg daily, if necessary, to achieve target serum urate goals. Although there is no level of renal function below which probenecid and sulfapyrazone are known to completely lose efficacy,⁴⁴ these drugs appear to be substantially less effective in patients with moderate to severe renal insufficiency ($\text{CrCl} < 60 \text{ mL/min}$).⁸⁶ Loss of hypouricemic effect with these agents with advancing renal impairment limits their utility in gout,

given the relatively high prevalence of impaired renal function in this population.⁸⁷

In contrast to probenecid and sulfapyrazone, benzbromarone is administered once daily and may be effective even in patients with moderate renal impairment. Benzbromarone treatment in usual doses (50 to 200 mg/day) leads to between 25% and 50% reductions in circulating UA,^{88–91} in addition to decreases in gout flare rates and dissolution of tophi.^{92–94} In a randomized controlled trial, benzbromarone maintained its hypouricemic effect even among patients with a CrCl as low as 20 to 40 mL/min.⁹¹ Among patients intolerant to or experiencing treatment failure with allopurinol 300 mg/day, 92% of those administered benzbromarone (200 mg/day) achieved a serum urate level less than 5.0 mg/dL compared with 65% of those receiving probenecid (2000 mg/day).⁹⁵

Uricosurics may also serve as effective adjuvants to XO inhibition. Although uricosurics enhance excretion of oxypurinol, the active metabolite of allopurinol, their effect on oxypurinol clearance⁵⁴ does not appear to negate the additive urate-lowering effect gained by using these medications in combination. For instance, among patients failing allopurinol monotherapy (200 to 300 mg/day), 86% achieved a target serum urate goal of less than 5 mg/dL after the addition of probenecid (1000 mg/day).⁹⁶ Likewise, the combination of benzbromarone and allopurinol has been shown to

have a more potent urate-lowering effect than allopurinol alone, and the combination has been shown to yield more rapid resolution of tophi than allopurinol monotherapy.⁹⁴

Toxicity

As with other ULTs, rebound gout flares represent a common complication of uricosurics. Because urinary UA acts as a potential nidus for stone formation, uricosuric therapy is associated with increased risk of nephrolithiasis. In a recent longitudinal study including more than 780 patient-years of benzbromarone exposure, approximately 10% (21 of 216) of patients developed nephrolithiasis.⁹⁷ Of the 21 patients with incident nephrolithiasis, 7 developed oxalate stones and 14 developed stones composed of UA or a combination of UA and calcium. In addition to limiting uricosurics to patients underexcreting UA, the risk of treatment-related nephrolithiasis can be mitigated by optimizing fluid intake and alkalinizing the urine with a goal of maintaining a urine pH greater than 6.0.⁹⁸ Other adverse effects observed with uricosurics are summarized in Table 65-1. Rare side effects associated with uricosurics have included anaphylaxis, anemia (including aplastic and hemolytic anemia), other cytopenias, fever, nephrotic syndrome, and back pain. Rare reports of severe liver injury led to the withdrawal of benzbromarone by its primary manufacturer in 2003, a decision recently challenged in systematic risk-benefit analyses of the drug.⁴⁴ Owing to its NSAID-like properties, sulfinpyrazone has been associated with an increased frequency of blood dyscrasia (rare), in addition to upper GI disturbances including peptic ulcer disease.⁹⁹

Fertility, Pregnancy, and Lactation

Limited data are available regarding the impact of uricosurics on fertility, fetal development, and use in nursing infants; thus, these agents should be used with caution in such patients only when the potential benefits of treatment outweigh its potential risks.

Drug Interactions and Contraindications

Given that tubular secretion plays a central role in the renal clearance of numerous drugs, drug-drug interactions are well recognized with the use of uricosurics, particularly probenecid (see Table 65-1). Inhibition of tubular drug secretion appears to be greater for probenecid and sulfinpyrazone than for benzbromarone owing to increased URAT1 “specificity” of the latter agent. Drug interactions observed with uricosurics are summarized in Table 65-1.

As with all ULTs, uricosurics should not be initiated during an acute gout flare and should not be used in patients with known allergies to these agents. Because of the potential for cross-reactivity, sulfinpyrazone should be avoided in patients with allergies to phenylbutazone or other pyrazole compounds. Except under special circumstances, these agents should be avoided in patients with nephrolithiasis or evidence of UA overexcretion, and during cancer treatment, including chemotherapy or radiation. Caution should also be used in patients with known blood dyscrasias, active peptic ulcer disease, or significant hepatic or renal disease.

URICASES

Pegloticase

KEY POINTS

Pegloticase facilitates the conversion of UA into allantoin, which is far more soluble.

Intravenous administration of pegloticase is associated with rapid and marked declines in serum UA concentration.

Drug-related antigenicity represents a major limitation in the repeated dosing of pegloticase.

Pegloticase, a modified mammalian uricase, is a biologic parenterally administered agent that represents the most recently approved ULT in gout. Unlike other mammalian species, humans have lost the ability to synthesize functional uricase that converts UA into allantoin, the latter being 5 to 10 times more soluble. Use of alternative uricases (e.g., rasburicase—a recombinant uricase from *Aspergillus flavus*¹⁰⁰) in the treatment of tumor lysis syndrome has been substantially limited by drug-related antigenicity and prohibitively high rates of anaphylaxis with repeat drug administration. In contrast to older-generation uricases, pegloticase appears to be less allergenic and has been administered successfully to many patients in repeated intravenous infusions.

Role in Rheumatic Disease and Indications

Pegloticase is approved for the treatment of hyperuricemia in patients with treatment-refractory gout. Approved with an orphan drug status in the United States, pegloticase is indicated in a small subset of gout patients. Treatment-refractory disease is characterized by severe disabling gout, often accompanied by significant comorbid illness, in which conventional ULT may be contraindicated or ineffective.¹⁰¹ Pegloticase administration is associated with rapid and marked declines in serum UA; in clinical trials, pegloticase use resulted in serum UA reduction with nadirs as low as 0.5 to 1 mg/dL within 24 hours of an initial dose.^{102,103} As a consequence, pegloticase administration has been associated with dramatic regression of tophi and depletion of urate stores, raising speculation that pegloticase or other uricase formulations could play a role as an “induction” therapy in select patients with severe tophaceous gout.

Chemical Structure and Mechanism of Action

Pegloticase is a recombinant mammalian uricase linked to polyethylene glycol (PEG). Pegloticase facilitates the conversion of UA into allantoin. The conversion of allantoin from UA generates hydrogen peroxide (H₂O₂) that is scavenged by erythrocytes and thus does not appear to increase levels of oxidative stress.¹⁰⁴

Pharmacology

The pharmacokinetics of pegloticase follows a one-compartment linear model. Maximum serum concentrations and the magnitude of the urate-lowering effect

following intravenous pegloticase administration increase in a dose-dependent fashion.¹⁰³ Pegloticase pharmacokinetics are not affected by age, sex, weight, or underlying renal function. A single dose of pegloticase (≥ 2 mg) has been shown to have a highly variable duration of effect, suppressing serum urate concentrations below 7.0 mg/dL for periods ranging from 1 to 8 days.¹⁰³ The high degree of variability in drug elimination and treatment durability appears to be related at least in part to the presence and concentration of circulating anti-pegloticase antibody (see later).

Dose and Drug Administration

Pegloticase is approved for intravenous infusion at a dose of 8 mg every 2 weeks (see Table 65-1). The agent is administered as a 2-hour infusion. Regulatory approval of pegloticase is based on results from two 6-month replicate randomized placebo-controlled studies, in addition to open-label follow-up extensions (N = 212 total).¹⁰⁵ Patients in these clinical trials had pretreatment serum urate concentrations exceeding 8.0 mg/dL and had symptomatic gout with failure of prior allopurinol therapy based on reported intolerance or ineffectiveness at a “maximum medically appropriate dose.” Patients received prophylaxis against infusion reactions (see Table 65-1) and against rebound gout flares (colchicine, NSAID, or glucocorticoid). The primary outcome for both randomized studies was a serum UA less than 6.0 mg/dL for 80% of more of the sampling period from month 3 to month 6 of follow-up. This outcome was met by 47% and 38% of subjects receiving pegloticase 8 mg intravenously (IV) every 2 weeks in the two randomized studies. In pooled analyses, 40% of subjects with baseline tophi who received pegloticase 8 mg every 2 weeks (vs. 7% of those receiving placebo) had complete resolution of their tophi by the time of the final study visit.

Although nonresponders and responders generally achieved similarly striking plasma urate reductions following their initial pegloticase infusion, nonresponders generally “lost” treatment effect within the first 3 months of therapy. Efficacy loss, reflected in serum UA rising above 6.0 mg/dL during treatment, appears to be strongly associated with the formation of anti-pegloticase antibodies (primarily immunoglobulin [Ig]M and IgG subtypes binding the PEG portion of the drug). Clinically meaningful manifestations of anti-pegloticase antibody formation, including increased risk of anaphylaxis and neutralization of drug effect, appear to be most striking at antibody titers exceeding 1:2430. It is recommended that serum urate levels, rather than drug antibody titers, be monitored closely during treatment, with discontinuation of pegloticase if serum UA increases above 6.0 mg/dL.¹⁰⁵

Toxicity

The most common serious adverse event observed with pegloticase therapy is anaphylaxis, observed in approximately 7% of patients (see Table 65-1). Anti-pegloticase antibody can be detected in a vast majority of patients ($\approx 90\%$) receiving treatment, although “clinically meaningful” antibody titers are encountered less often. In clinical studies, anaphylaxis occurred despite prophylaxis that included antihistamine and glucocorticoid therapy with

onset of symptoms typically seen within 2 hours of drug administration. Treatment-related anaphylaxis is far more common among patients with treatment failure; thus, close serum UA surveillance and discontinuation of pegloticase for patients with serum UA greater than 6.0 mg/dL are essential elements in risk mitigation. Given overlap with symptoms of anaphylaxis, infusion reactions occur in up to 25% of patients receiving pegloticase with manifestations that include urticaria, dyspnea, chest discomfort/pain, erythema, and pruritus. Infusion reactions can occur at any time in the course of therapy, and rare reports have described delayed hypersensitivity reactions.

As with other ULTs, rebound gout flare is common following administration of pegloticase. Other adverse events observed with pegloticase are summarized in Table 65-1. In clinical studies and in open-label follow-up, exacerbations of congestive heart failure were also more common with pegloticase than placebo, although a causal association with active drug therapy has not been established.¹⁰⁵

Fertility, Pregnancy, and Lactation

No studies have examined the impact of pegloticase on fertility or pregnancy in humans, and it is unknown whether pegloticase is excreted in human milk. In the absence of appropriate human studies, pegloticase is classified as Pregnancy Category C, and it is not recommended for use in nursing mothers.

Drug Interactions and Contraindications

Given that anti-pegloticase antibodies bind the PEG portion of the agent, pegloticase should be used with caution in patients receiving other PEG-containing therapies. Whether the formation of anti-pegloticase antibodies precludes or impacts future treatment with other PEGylated molecules is unknown. Pegloticase is contraindicated in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency owing to increased risks of hemolysis and methemoglobinemia; patients at increased risk should be screened for G6PD deficiency before initiation of treatment.¹⁰⁵

URATE-LOWERING DRUGS IN DEVELOPMENT

The treatment armamentarium in chronic gout will likely grow in the future with several novel ULTs under development, including uricosurics, uricases, and agents inhibiting endogenous UA synthesis.

Inhibitors of UA Synthesis

BCX4208 represents a potentially novel mechanism inhibiting endogenous UA synthesis via inhibition of purine nucleoside phosphorylase (PNP). Along with adenosine deaminase, PNP plays a role in purine degradation, acting “proximally” to XO by metabolizing inosine into hypoxanthine. In a 3-week study of 60 gout patients (all with baseline serum UA >8.0 mg/dL), 31% to 36% of patients given BCX4208 (40 mg, 80 mg, and 120 mg daily) achieved a

final serum UA less than 6.0 mg/dL.¹⁰⁶ Corresponding decreases in serum urate ranged from 2.7 to 3.4 mg/dL compared with a decline of just 0.4 mg/dL with placebo. The potential immunosuppressive effects of BCX4208, which were well tolerated in this short-term study, warrant further study, given that inherited PNP deficiency results in severe combined immunodeficiency.

Uricosuric Agents

Lesinurad (formerly RDEA 594) is a metabolite of RDEA 806, a non-nucleoside reverse transcriptase inhibitor. Lesinurad appears to specifically inhibit URAT1, lacking significant effects on other organic anion transporters (see Figure 65-3).¹⁰⁷ Selective URAT1 inhibition may limit drug interactions that complicate probenecid use. In contrast to probenecid,⁵⁴ the co-administration of lesinurad does not appear to increase the renal elimination of oxypurinol or febuxostat,¹⁰⁸ suggesting that this may be an ideal uricosuric for use in combination. In a recent study, the addition of lesinurad to allopurinol (300 mg/day) led to dose-dependent declines in serum UA.¹⁰⁹

In addition to displaying urate-lowering properties, tranilast has been studied for possible therapeutic effects in a number of conditions, including allergy, malignancy, and conditions characterized by excessive tissue fibrosis. Similar to those of currently available uricosurics, the urate-lowering effects of tranilast are mediated through inhibition of URAT1 and GLUT9 transporters (see Figure 65-3).¹¹⁰ In a recent study, tranilast administration (300 mg/day) was associated with a 14% decline in serum UA, with 28% of patients achieving a serum UA less than 6.0 mg/dL.¹¹¹

Uricases

Pegsiticase is a recombinant uricase derived from *Candida utilis*, conjugated to PEG. Pegsiticase has been examined in an open-label, single-dose (0.05 to 0.4 mg/kg IV) escalation study in 20 gout patients.¹¹² In this study, pegsiticase was well tolerated, with gout flare representing the most common adverse event. Rapid and marked declines in serum UA were observed in all patients, and UA concentrations decreased to below 2.0 mg/dL for 7 to 24 days in a dose-dependent fashion. The degree to which immunogenicity reduces the long-term effectiveness of this agent awaits further study.

KEY POINTS

Numerous analgesic agents can be used in the treatment of pain related to rheumatic disease.

The primary analgesic agents such as acetaminophen, nonsteroidal anti-inflammatory agents, and opioids have intrinsic analgesic properties that are most efficacious for nociceptive and inflammatory pain.

Adjuvant agents such as antidepressants, anticonvulsants, and muscle relaxants lack intrinsic analgesic properties but are effective in neuropathic and functional pain and can enhance effects of other analgesics.

The use of opioids for chronic pain remains controversial, but with proper patient selection and adherence to Universal Precautions, risks can be minimized and benefits maximized.

Many drugs can increase and decrease the metabolism of opioids through interaction of CYP2D6 and CYP3A4 systems. This can greatly vary the effects of opioid in different individuals.

Increased reports of methadone overdose are thought to be due to co-administration of drugs that inhibit the CYP3A4 system.

Although the tricyclic antidepressants have been shown to be efficacious in a variety of pain syndromes, compliance is an issue because of unacceptable side effects and delayed onset.

Newer serotonin and norepinephrine reuptake inhibitors (such as duloxetine) are better tolerated and have a faster onset than older tricyclic antidepressants.

Numerous anticonvulsants have been studied with conflicting results. Only gabapentin and pregabalin consistently demonstrated efficacy in double-blind, placebo-controlled studies.^{1,2}

Muscle relaxants are intended for short term use only and have not been shown to have long benefits.

Pain is the most common reason why patients seek medical attention, yet undertreatment of acute and chronic pain persists despite decades of efforts to provide clinicians with information about analgesics.^{3,4} A major consequence of undertreating the patient who initially presents with pain as a result of rheumatic disease is the development of chronic pain. Chronic pain has been demonstrated to have deleterious effects on many aspects of the patient's daily life. These effects include deterioration in physical functioning, the development of psychologic distress and psychiatric disorders, and impairments in interpersonal functioning.^{5,6} In addition to the personal suffering it causes, chronic pain

Analgesic Agents in Rheumatic Disease

GREGORY R. POLSTON • MARK S. WALLACE

imposes a burden on society in increased health care costs, disability, and lost workdays.

PHYSIOLOGY OF PAIN PERCEPTION (THE PAIN EXPERIENCE)

The "pain experience" involves more than just the sensation of pain. Pain activates many areas of the brain that interact, resulting in the pain experience, which will differ among individual patients. The three components of the pain experience include (1) sensory/discriminative, (2) affective/emotional, and (3) evaluative/cognitive.^{7,8}

The sensory/discriminative component of pain provides information on the intensity, location, and quality of the pain. These pathways consist of peripheral receptor activation, axon depolarization, and ascending pathways to the cortex for processing.

The ascending pathways that carry impulses from the nociceptor to the sensory cortex also give off fibers to brain stem structures and deep brain structures. Activation of these structures in the brain stem and deep brain will stimulate emotional and sympathetic responses from the individual, leading to the emotional/affective component of pain.

Finally, ascending pain pathways also send projections to the forebrain structures where the pain is processed on a cognitive and evaluative level, explaining why patients respond differently to pain based on culture, gender, and past experiences.

The main neurotransmitter in primary afferents is the excitatory amino acid glutamate. Activation of nociceptors causes the release of glutamate from presynaptic terminals in the spinal cord dorsal horn; this release acts on the ionotropic glutamate receptor amino-3-hydroxy-5-methylisoxazole-4-propionic acid postsynaptically to cause rapid depolarization of dorsal horn neurons and, if threshold is reached, action potential discharge.^{9,10}

PAIN CLASSIFICATION

Pain can be mechanistically divided into four classifications: nociceptive, inflammatory, functional, and neuropathic. Nociceptive pain is transient pain in response to a noxious stimulus that activates high threshold afferents. Nociceptive pain serves a protective function. Inflammatory pain is the spontaneous hypersensitivity to pain that occurs in response to tissue damage and inflammation (e.g., postoperative pain, trauma, arthritis). Functional pain is hypersensitivity to pain resulting from abnormal central processing of normal input (e.g., pathologic irritable bowel syndrome,

fibromyalgia). Neuropathic pain is spontaneous pain and hypersensitivity to pain that occurs in association with damage to or lesions of the nervous system (e.g., peripheral neuropathy, postherpetic neuralgia). Nociceptive pain and inflammatory pain are prevalent in rheumatic disease. Functional pain and neuropathic pain are probably less prevalent in rheumatic disease; however, both should always be considered because poorly controlled pain can lead to nervous system dysfunction and functional and neuropathic pain.¹¹

PHARMACOLOGIC TREATMENT OF CHRONIC PAIN

The efficacy of analgesics is dependent on the pain mechanism. Primary analgesics are more efficacious in nociceptive and inflammatory pain, whereas adjuvant agents are more efficacious in neuropathic and functional pain. Each pain classification involves different pain mechanisms, and within each classification are multiple different pain mechanisms.^{12,13}

Pain is mediated through both peripheral and central mechanisms, and often more than one mechanism of pain is active in a given patient. Thus, the use of two or more agents with differing mechanisms increases the likelihood of interrupting pain signals and relieving pain.

Pharmacologic agents for the management of chronic pain are divided into primary analgesics, which have intrinsic analgesic properties, and adjunct analgesics, which may have primary analgesic properties in neuropathic pain but usually enhance the analgesic effects of primary analgesics when used in non-neuropathic pain syndromes. Table 66-1 summarizes these agents. Nonsteroidal anti-inflammatory drugs (NSAIDs)/cyclooxygenase (COX)-2 inhibitors will be discussed elsewhere (see Chapter 59).

OPIOIDS

Numerous studies have demonstrated the efficacy of the opioids in a variety of chronic pain states, including neuropathic and non-neuropathic. However, studies to document long-term efficacy have not been conducted. Long-term opioid therapy to treat chronic pain remains controversial. Over the last century, the pendulum has swung back and forth with regard to the use of the opioids to treat pain. In the mid 20th century, opioids were limited because of fears of addiction and diversion. In the late 20th century, the pendulum went to the other side with liberal use of opioids to treat chronic pain. With the turn of the 21st century, the pendulum is moving back toward the middle with

Table 66-2 Universal Precautions for Long-term Opioid Use to Treat Pain

Diagnosis with appropriate differential
Psychologic assessment, including risk of addictive disorders
Informed consent
Treatment agreement
Preintervention and postintervention assessment of pain level and function
Appropriate trial of opioid therapy with or without adjunctive medication
Reassessment of pain score and level of function
Regular assessment of the “4 A’s” (analgesia, activities of daily living, adverse effects, aberrant drug-taking behaviors)
Periodic review of pain diagnosis and comorbid conditions, including addictive disease
Documentation

recognition of the importance of opioids in chronic pain management but an understanding of the need to balance these benefits with risks. Recently published guidelines acknowledge that opioid analgesics have an important role in pain management, and that underuse of these agents may contribute to suboptimal pain management.¹⁴ However, these guidelines also acknowledge that abuse of prescription opioids has become an epidemic, with dramatic increases seen in the United States. Therefore, a set of Universal Precautions have been developed as a guide to help the physician who prescribes opioids¹⁵ (Table 66-2).

After conservative treatments, including nonopioids, have failed to control the patient’s pain, an opioid should be considered. In general, a short-acting weak opioid such as hydrocodone or codeine should be used first. If the patient is requiring more than three or four short-acting weak opioids per day, consider converting to a long-acting opioid. Controlled-release or long-acting opioids not only provide convenience to patients by reducing the number of daily doses required, they also provide a pharmacokinetic profile that results in reduced serum level peaks and troughs, and thereby an improvement in the consistency of effective analgesia and a potential reduction in opioid-related side effects that are often correlated with high peak serum levels. When converting to a long-acting opioid, access to a short-acting opioid for breakthrough pain can be continued, but monitored and controlled. Evaluation by a pain specialist may be considered when morphine equianalgesic dosages exceed 90 mg/day. The benefits of levels higher than 180 mg/day have not been established, and recent evidence suggests a significant increase in morbidity and mortality when doses exceed 100 mg/day.¹⁶

Opiate Receptor Classes

Early work by Martin and associates led to the postulation of three opiate receptors: mu, kappa, and sigma.^{17,18} Later studies by Kosterlitz and colleagues led to the identification of the delta opioid receptor.¹⁹ With the exception of the sigma receptor, all of the opiate receptors are responsible for opioid-induced analgesia. Opioid receptors are mediated through a G protein, leading to a cascade of events that typically inhibit neuron activation.²⁰ Persistent activation of G protein-coupled receptors typically results in progressive loss of effect, known as *tolerance* (discussed later).

Table 66-1 Analgesic Options to Treat Chronic Pain

Primary Analgesics	Adjunct Analgesics
Acetaminophen	Tricyclic antidepressants
Nonsteroidal anti-inflammatory drugs/cyclooxygenase-2 inhibitors	Serotonin-norepinephrine reuptake inhibitors
Opioids	Anticonvulsants
	Muscle relaxants
	Topical agents

Opiate Receptor Distribution and Mechanisms of Opioid-Induced Analgesia

The main sites of action of the opiates are believed to be located in the brain and spinal cord; however, under some circumstances, peripheral mechanisms are involved. Responses of an individual patient may vary dramatically with different mu-opioid receptor (MOR) agonists. If problems are encountered with one drug, another should be tried. Mechanisms underlying variations in individual responses to morphine-like agonists are poorly understood; however, they are thought to be due to MOR polymorphisms.

Numerous sites in the brain have MORs. Activation of receptors located in the mesencephalic periaqueductal gray (PAG) appears to be the most important cause of opioid-induced analgesia. MOR agonists block release of the inhibitory transmitter γ -aminobutyric acid (GABA) from tonically active PAG systems that regulate activity in projections from the PAG to the medulla. This results in an increase in PAG outflow to the medulla, leading to activation of medullospinal projections and release of noradrenaline or serotonin at the level of the spinal dorsal horn. This release can attenuate dorsal horn excitability and analgesia. PAG activation can also increase the excitability of the dorsal raphe and the locus coeruleus, from which ascending serotonergic and noradrenergic projections originate to project to the limbic forebrain, leading to the euphoric effects sometimes experienced with systemic MOR agonists.²¹

In the spinal cord, MOR agonists are limited for the most part to the substantia gelatinosa of the superficial dorsal horn, the region in which small, high-threshold sensory afferents terminate. Most of these opiate receptors are located presynaptically and postsynaptically on small peptidergic primary afferent C fibers. Presynaptic activation of the MOR prevents the opening of voltage-sensitive Ca^{2+} channels, thereby preventing transmitter release. Postsynaptic activation of the MOR increases potassium conductance, resulting in hyperpolarization and reduced excitation induced by the presynaptic release of glutamate.²² The ability of spinal opiates to reduce the release of excitatory neurotransmitters from C fibers presynaptically and to decrease the excitability of dorsal horn neurons postsynaptically is believed to account for powerful and selective effects upon spinal nociceptive processing. In humans, an extensive literature indicates that a variety of opiates delivered spinally (intrathecally or epidurally) can induce a powerful analgesia.²²

Systemic delivery of the opioids will reduce nociceptive pain through a central mechanism located in the brain and spinal cord, as described previously, whereas the peripheral application has no effect. However, under conditions of inflammation, which result in an exaggerated pain response (hyperalgesia), the peripheral application of the opioids will reduce the hyperalgesia. This action is believed to be mediated by opiate receptors on the peripheral terminals of small primary afferents that become active under inflammatory conditions. Whether the effects are uniquely on the afferent terminal or on inflammatory cells that release products that sensitize the nerve terminal is not known.²³

Tolerance

Over time, a given dose of an opioid shows less effect and an increased dose is required to produce the same physiologic response. Tolerance to different effects of opioids occurs at different rates. For example, tolerance to sedation and nausea occurs earlier than analgesic tolerance. Some effects, such as constipation, never show tolerance.

The mechanism of opioid tolerance is controversial. Apparent opioid tolerance may be an indication of disease progression with a resultant increase in pain intensity; this is the first event that should be ruled out before true tolerance is assumed. Many cellular mechanisms can lead to tolerance. First, long-term opioid exposure can lead to receptor internalization, dephosphorylation, and desensitization. Second, exposure to high doses of opioids can lead to an increase in intracellular cyclic adenosine monophosphate (cAMP), activation of bulbospinal pathways, and glutamate receptor phosphorylation, producing an excitatory state (opioid-induced hyperalgesia).^{24,25} An incomplete cross-tolerance occurs between the various opioids, and when tolerance develops to one opioid, switching to another opioid can result in an increased effect.

Physical Dependence

Physical dependence is not addiction (and the terms should not be used interchangeably). Physical dependence is a pharmacologic effect characteristic of a number of different types of medications. Physical dependence is defined as the occurrence of an abstinence syndrome (withdrawal reaction) following abrupt discontinuation of the drug, substantial dose reduction, or administration of an antagonist. Physical dependence is generally assumed to occur with regular opioid use for as brief a period as a few days.

Opioid withdrawal is manifested by significant somatomotor and autonomic outflow (reflected by agitation, hyperalgesia, hyperthermia, hypertension, diarrhea, pupillary dilation, and release of virtually all pituitary and adrenomedullary hormones) and by affective symptoms (dysphoria, anxiety, and depression).²⁶ Opioid withdrawal can be minimized by slowly tapering the opioid. These phenomena are considered to be highly aversive and motivate the drug recipient to make robust efforts to avoid the withdrawal state. Initially, drug addicts are driven to repeated doses of opioids owing to the euphoric effects. However, over time, the euphoric effects are lessened, and addicts are driven to continue use to avoid withdrawal.

Addiction

Identification of the disease of addiction is important for safe and effective clinical management of pain in individuals with addictive disorders. The disease of addiction affects approximately 10% of the general population, and its prevalence may be higher in subpopulations of patients with pain. Active addiction is a contraindication to the use of the opioids; a past history is a relative contraindication, but opioids can be used successfully with appropriate monitoring. A persistent misunderstanding is prevalent among health care providers, regulators, and the general population regarding the nature and manifestations of addiction,

which may result in undertreatment of pain and stigmatization of patients using opioids for pain control.

Evaluating for addiction in a patient who is prescribed long-term opioids for pain control is often problematic. This risk of opioid addiction and misuse can be assessed with validated questionnaires (Table 66-3).²⁷ Although the concept of addiction may include the symptoms of physical dependence and tolerance, physical dependence or tolerance alone does not equate with addiction. In the chronic pain patient taking long-term opioids, physical dependence and tolerance should be expected, but the maladaptive behavior changes associated with addiction are not expected.^{28,29}

Addiction is a behavioral pattern characterized by compulsive use of a drug and overwhelming involvement with its procurement and use in spite of potential harm. For patients with continuous pain, inadequate pain management (e.g., PRN dosing schedule, use of drugs with inadequate potency, use of dosing intervals that are too long) can lead to behavioral symptoms that mimic those seen with psychological dependence and can be mistaken for addiction termed *pseudoaddiction*. In the case of pseudoaddiction, problem behaviors resolve after sufficient pain relief is established. However, behaviors related to true addiction may also resolve after dose escalation. Thus, it can be difficult to distinguish pseudoaddiction from true addiction; careful evaluation and management may be required until the circumstances are sorted out³⁰ (see Table 66-3).

Opioid Pharmacology

Morphine

Morphine is the gold standard against which all other opioids are measured. Morphine can be administered by

oral, rectal, subcutaneous, intravenous, intramuscular, and intraspinal routes. Oral bioavailability of morphine is about 25% (range, 10% to 40%). Peak plasma concentrations occur 0.5 to 1 hour after ingestion with a half-life of around 3 to 4 hours. To increase the dosing interval of oral morphine, several sustained- and controlled-release preparations have been developed (Table 66-4). The average protein binding of morphine is around 35%, but this decreases with renal and hepatic dysfunction. Because of the hydrophilicity of morphine, there is poor central nervous system (CNS) penetration and little tissue accumulation with repeated dosing. Morphine is metabolized primarily in the liver to two main metabolites: morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). M3G is the primary metabolite with potent CNS excitatory properties. Because of its polarity, CNS penetration is poor; however, in renal failure, M3G plasma concentrations can be high enough to drive this metabolite into the CNS, leading to excitation. M6G possesses potent MOR agonism, but because of its high polarity, CNS penetration is poor. However, like M3G, M6G can accumulate in renal impairment, leading to exaggerated opioid effects. Only about 10% of unmetabolized morphine is excreted renally, whereas 90% is excreted renally as morphine glucuronide (70% to 80%) and normorphine (5% to 10%) conjugates.³¹

Methadone

Methadone is a long-acting MOR agonist with potency similar to that of morphine but with two important differences: (1) It has a long half-life, and (2) it has high oral bioavailability. Routes of administration are oral and intravenous, with oral delivery being by far the most common. Intravenous routes have been used as a single loading dose for postoperative pain control. Because of its low hepatic

Table 66-4 Opioid Drug Interactions

Tramadol, oxycodone, hydrocodone, and codeine are converted to active metabolites by CYP2D6
Drugs that inhibit this enzyme will decrease opioid effects: fluoxetine, paroxetine, quinidine, duloxetine, terbinafine, amiodarone, sertraline, and others
Methadone and fentanyl are converted by CYP3A4
Drugs that inhibit this enzyme will increase opioid effects: several antiretrovirals, clarithromycin, itraconazole, ketoconazole, nefazodone, telithromycin, aprepitant, diltiazem, erythromycin, fluconazole, grapefruit juice, verapamil, cimetidine, and others
Morphine, hydromorphone, and oxymorphone are not significantly metabolized by CYP450 isoenzymes

From Daniell H: Inhibition of opioid analgesia by selective serotonin reuptake inhibitors, *J Clin Oncol* 20:2409, 2002; U.S. Food and Drug Administration: www.fda.gov/cder/drug/drugInteractions <http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?cid=2284>; <http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=9154>; http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=134337548&loc=es_rss; http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=134337351&loc=es_rss; http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=134338168&loc=es_rss; http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=134224843&loc=es_rss; http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=134223868&loc=es_rss; <http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=126652570>; http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=134338226&loc=es_rss; and http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?sid=49969196&loc=es_rss.

clearance and therefore low first-pass effect, oral bioavailability is around 80%. Methadone has higher lipid solubility than morphine, which results in faster CNS penetration and onset of action; however, its lipid solubility leads to a higher volume of distribution and a shorter duration of action with initial dosing. Low hepatic clearance leads to accumulation, a longer duration of action, and possible overdose with repeated dosing.

Because of the long half-life of methadone (average, 15 to 30 hours, with published reports ranging from 8 to 59 hours) with drug accumulation over several days, methadone needs to be administered with caution with long intervals between dose adjustments (5 to 7 days). Deaths have been reported with the use of methadone for chronic pain, and in November 2006, the U.S. Food and Drug Administration (FDA) issued a public health advisory for methadone with a black box warning. Although details are often unclear, many of these deaths may be due to conversion of patients from other opioids to methadone. Methadone has been associated with QRS prolongation, which can lead to sudden cardiac death. If unfamiliar with the use of methadone, it is advisable to seek consultation with a pain specialist, especially when considering prescribing methadone at greater than a low dose (20 to 30 mg/day).^{32,33}

The L-isomer of methadone possesses opioid activity, whereas the D-isomer is weak or inactive as an opioid. Evidence suggests that D-methadone is antinociceptive as a result of its N-methyl-D-aspartate (NMDA) receptor antagonist activity, making methadone attractive in treating neuropathic pain.³⁴

Methadone is metabolized primarily by CYP3A4, secondarily by CYP2D6, and to a smaller extent by CYP1A2 and additional enzymes that are under study. CYP3A4, the most abundant metabolic enzyme in the body, can vary 30-fold between individuals in terms of its presence and activity in the liver. In addition, drugs that inhibit this enzyme (several antiretrovirals, clarithromycin, itraconazole, ketoconazole, nefazadone, telithromycin, aprepitant, diltiazem, erythromycin, fluconazole, grapefruit juice, verapamil, cimetidine, and others) will increase the effect of methadone, possibly leading to overdose. This enzyme is also found in the gastrointestinal tract, so methadone metabolism actually starts before the drug enters the circulatory system. The amount of this enzyme in the intestine can vary up to 11-fold, partially accounting for the variable breakdown of methadone.³⁵

Because the half-life of methadone is so long, it has been used extensively to treat opioid dependence and withdrawal. The use of methadone to treat addiction requires a separate clinic and physician license. However, methadone can be used to treat pain under the routine medical Drug Enforcement Administration (DEA) license.

Fentanyl

Fentanyl is a potent opioid with very high lipid solubility. This high lipid solubility leads to fast onset, a short duration of action, high protein binding (80%), and a high volume of distribution. The high volume of distribution accounts for the short duration of action owing to the high

concentration gradient from the plasma to fat and muscle. However, with repeated dosing, the duration of action increases as fat and muscle stores become saturated with fentanyl. Although the analgesic half-life is around 1 to 2 hours, the terminal half-life is about 3 to 4 hours.³⁶

Routes of delivery of fentanyl include transdermal, transmucosal, intravenous, and intraspinal. Subcutaneous delivery is also used in terminal cancer patients. High potency and lipid solubility make fentanyl ideal for transdermal and transmucosal delivery. Two transdermal fentanyl patches are available on the market: reservoir and matrix. The reservoir patch can be accessed and the fentanyl extracted, whereas the matrix patch is tamper-proof. Each system delivers fentanyl over 72 hours; however, some patients will deplete the patch within 48 hours, requiring more frequent patch changes. This variability can result from skin perspiration, fat stores, skin temperature, and muscle bulk. After application, the skin serves as a depot, and systemic levels rise for the next 12 to 24 hours, then remaining stable until 72 hours. Peak concentration occurs somewhere between 27 and 36 hours (25 mg 27 hours, 100 µg 36 hours). A steady state is reached after several applications. After removal of the system, plasma concentrations fall by 50% over 17 hours.³⁷

Three transmucosal products are currently available. The fentanyl oralet contains fentanyl in a base of food starch, confectioners' sugar (2 g vs. 30 g in a Snickers bar), edible glue, citric acid, and artificial berry flavor. The oralet is placed between the gum and the cheek and is allowed to dissolve over 15 minutes with bioavailability of about 50%. Onset is fast, with a peak effect at about 35 minutes. The fentanyl buccal tablets use an oravescent delivery system that generates a reaction that releases carbon dioxide when the tablet comes in contact with saliva. Transient pH changes accompanying the reaction optimize the dissolution (at a lower pH) of fentanyl through the buccal mucosa. Onset is fast with a peak effect at about 25 minutes. The Bio-Erodable Muco Adhesive (BEMA) fentanyl delivery system is composed of water-soluble polymeric films. This system consists of a bioadhesive layer bonded onto an inactive layer. The active ingredient, fentanyl citrate, is incorporated into the bioadhesive layer, which adheres to the moist buccal mucosa. The amount of fentanyl delivered transmucosally is proportional to the film surface area. It is believed that the inactive layer isolates the bioadhesive layer from the saliva, which may optimize delivery of fentanyl across the buccal mucosa, resulting in higher bioavailability (71%). Onset is fast with a slightly longer peak effect (60 minutes) as compared with the other transmucosal systems; however, there may be a longer duration. Chewing and swallowing any of the transmucosal fentanyl products results in lower bioavailability and peak effect because swallowed fentanyl is poorly absorbed from the gastrointestinal tract.³⁸

Fentanyl is metabolized primarily by CYP3A4 to the inactive metabolite norfentanyl; therefore, drugs that inhibit this enzyme will increase the drug effect (see earlier under "Methadone"). Only opioid-tolerant patients (>60 mg/day of oral morphine equivalent) should be started on fentanyl products owing to risks of severe respiratory depression.

Oxycodone and Oxymorphone

Oxycodone is administered by the oral or rectal route. Oral bioavailability is 60% and protein binding, 45%. Onset and duration of action are similar to morphine. Oxycodone is metabolized by the CYP3A4 enzyme primarily to noroxycodone, which has about 25% potency of the parent compound but also has neuroexcitatory effects. Minor metabolites include oxymorphone, which is more potent than oxycodone and has a longer half-life, and noroxymorphone, which has no analgesic properties.³⁹

Oxycodone is available as an immediate-release tablet or solution and as a controlled-release preparation. The controlled-release preparation has an immediate release effect of up to 40% of the contents, followed by a sustained 12-hour release component. The immediate release effect results in rapid onset followed by a sustained effect. This can be a disadvantage because the patient may perceive the duration as short when coming down from the high peak plasma concentration caused by the immediate release.

Oxymorphone is a metabolite of oxycodone and can be delivered via the oral and rectal routes. Both bioavailability and protein binding are low (10%), but terminal half-life is long (10 to 12 hours). Most of the oxymorphone is metabolized to oxymorphone-3-glucuronide, which is an inactive metabolite. Oxymorphone is available in immediate-release and sustained-release preparations.⁴⁰

Hydromorphone

Hydromorphone is administered by the oral, intravenous, intramuscular, and subcutaneous routes. Oral bioavailability is low (ranging from 25% to 50%), and protein binding is less than 20%. The kinetics are very similar to morphine. Hydromorphone has an extensive first-pass effect, and 95% is metabolized to the inactive hydromorphone-3-glucuronide. A 24-hour-release preparation of hydromorphone has been approved by the FDA. This preparation uses an osmotic piston-driven system in pill form that slowly delivers hydromorphone over 24 hours.⁴¹

Meperidine

Meperidine can be delivered by the oral, rectal, intravenous, intramuscular, subcutaneous, and intraspinal routes. Meperidine use has decreased over time owing to side effects and risks associated with the parent compound and metabolites (see later). Oral bioavailability is about 50%, protein binding is about 60%, and peak concentrations in plasma usually are observed in 1 to 2 hours. Onset and duration are similar to morphine. Large doses of meperidine repeated at short intervals may produce an excitatory syndrome that includes hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are caused by accumulation of the metabolite, normeperidine, which has a half-life of 15 to 20 hours compared with 3 hours for meperidine. Because normeperidine is eliminated by the kidney and the liver, decreased renal or hepatic function increases the likelihood of such toxicity. As a result of these properties, meperidine is not recommended for the treatment of chronic pain because of

concerns over metabolite toxicity. It should not be used for longer than 48 hours or in doses greater than 600 mg/day.^{42,43}

Severe reactions may follow the administration of meperidine to patients being treated with monoamine oxidase (MAO) inhibitors. Two basic types of interactions can be observed. The most prominent is an excitatory reaction ("serotonin syndrome"). This reaction may be due to the ability of meperidine to block neuronal reuptake of serotonin and resulting serotonergic overactivity. Another type of interaction, a potentiation of opioid effect due to inhibition of hepatic CYPs, also can be observed in patients taking MAO inhibitors, necessitating a reduction in the doses of opioids.

Hydrocodone

Hydrocodone is a weak MOR agonist. It is delivered only by the oral route and is available only in acetaminophen-containing compounds, thus making it a Schedule III opioid. This has led to overutilization with reports of acetaminophen toxicity. Hydrocodone has an oral bioavailability of about 25% with low protein binding. It is metabolized to hydromorphone, but its analgesic activity is not dependent upon metabolism to hydromorphone. However, rapid metabolizers may experience a faster onset of action owing to the production of hydromorphone. Onset and duration of effect are similar to morphine.

Codeine

Codeine has an exceptionally low affinity for the MOR, and the analgesic effect of codeine is due to its conversion to morphine. The oral bioavailability is about 60% and is poorly protein bound. The onset and duration of effect are similar to morphine. It is administered via the oral route.

The conversion of codeine to morphine is effected by CYP2D6. Well-characterized genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as an analgesic for about 10% of the white population. Other polymorphisms can lead to enhanced metabolism and thus to increased sensitivity to the effects of codeine.⁴⁴ Variation in metabolic efficiency is evident among ethnic groups. For example, Chinese individuals produce less morphine from codeine than do whites and are less sensitive to the effects of morphine.⁴⁵

Tramadol

Tramadol is a synthetic codeine analogue with a dual mechanism of action. Analgesia results through weak MOR agonism and inhibition of uptake of norepinephrine and serotonin.

Tramadol is 68% bioavailable after a single oral dose with about 20% protein binding. Its affinity for the opioid receptor is only $\frac{1}{6000}$ that of morphine. However, the primary O-demethylated metabolite of tramadol is two to four times as potent as the parent drug and may account for part of the analgesic effect. Tramadol is supplied as a racemic mixture, which is more effective than either enantiomer alone. The

(+)-enantiomer binds to the receptor and inhibits serotonin uptake. The (–)-enantiomer inhibits norepinephrine uptake and stimulates α_2 -adrenergic receptors.⁴⁶ The compound undergoes hepatic metabolism and renal excretion, with an elimination half-life of 6 hours for tramadol and 7.5 hours for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2 to 3 hours. The duration of analgesia is about 6 hours. The maximum recommended daily dose is 400 mg. Tramadol is also available in an extended 24-hour release preparation.

Physical dependence on and abuse of tramadol have been reported. Although its abuse potential is unclear, tramadol probably should be avoided in patients with a history of addiction. Because of its inhibitory effect on serotonin uptake, tramadol should not be used in patients taking MAO inhibitors and triptans. Seizures have been reported with concomitant use of selective serotonin receptor inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and neuroleptics.⁴⁶

Tapentadol

Tapentadol is a strong opioid with a dual mechanism of action, similar to tramadol. It is a strong MOR agonist and a serotonin and norepinephrine reuptake inhibitor. Because of its first-pass metabolism, its bioavailability is low (32%) and protein binding is low (20%). The metabolites of tapentadol are inactive. The half-life is approximately 4 hours.

Similar to tramadol, tapentadol is contraindicated in patients taking MAO inhibitors, triptans, SSRIs, SNRIs, TCAs, and neuroleptics owing to risk of serotonin syndrome. There does not appear to be a risk of seizures, as is seen with tramadol. Tapentadol is currently available as an oral immediate-release drug; however, an extended-release preparation is in development (Figure 66-1).

Toxicity

Respiration

Although effects on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard analgesic doses in the absence of other contributing comorbidities or concomitant use of sedatives. In addition, the respiratory depressant effect of the opioid is significantly reduced with continued opioid use owing to tolerance. It should be stressed, however, that *respiratory depression represents the primary cause of morbidity secondary to opiate therapy*.⁴⁷ In humans, death from opiate poisoning is nearly always due to respiratory arrest or obstruction.⁴⁸ For example, In November of 2006, the FDA notified health care professionals of reports of death and life-threatening adverse events, such as respiratory depression and cardiac arrhythmias, in patients receiving methadone (FDA ALERT [11/2006]: Death, narcotic overdose, and serious cardiac arrhythmias, www.fda.gov/cder/drug/infopage/methadone). Methadone appears to be involved in approximately one-third of all prescription opioid-related deaths, exceeding hydrocodone and oxycodone despite being prescribed one-tenth as often. This has led to revisions in methadone conversion tables.

At therapeutic doses, opiates depress all phases of respiration (rate, minute volume, and tidal exchange). High doses can produce irregular and agonal breathing.⁴⁸ A number of factors can increase the risk of opioid-induced respiratory depression, even at therapeutic doses. These include (1) concomitant use of sedatives such as alcohol, benzodiazepines, and tranquilizers, (2) obstructive and central sleep apnea, (3) extremes in age (both newborns and elderly), (4) comorbidities such as pulmonary disease and renal disease, and (5) removal of the painful stimulus. Pain serves as a respiratory stimulant, and removal of pain (e.g., neurolytic block with severe cancer pain) will reduce the ventilatory drive, leading to respiratory depression.

Sedation

Opiates can produce drowsiness and cognitive impairment, which can increase respiratory depression. These effects most typically are noted following initiation of opiate therapy or after a dose increase but usually resolve with continued opioid use. If the sedation does not resolve, other causes of the sedation should be investigated, such as concomitant use of other sedatives or the presence of sleep apnea. In the absence of these variables, opioid rotation may result in less sedation.⁴⁹

Neuroendocrine Effect

Regulation of the release of hormones and factors from the pituitary is under complex regulation by opiate receptors in the hypothalamic-pituitary-adrenal (HPA) axis. The opioids block the release of a large number of many HPA hormones, including sex hormones, prolactin, oxytocin, growth hormone, and antidiuretic hormone.

In males, the opioids inhibit adrenal function, resulting in reduced cortisol production and reduced adrenal androgens. In females, the opioids lower luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release. In both males and females, long-term opioid therapy can result in endocrinopathies, including hypogonadotropic hypogonadism, leading to decreased libido, and females may develop menstrual cycle irregularities. These changes are reversible with removal of the opiate. Mechanisms of neuroendocrine effects of the opioids are thought to be due to a direct effect on the pituitary and an indirect action on the hypothalamus, blocking the release of gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH). Secretion of thyrotropin is relatively unaffected.

Opioids inhibit the release of dopamine from neurons of the tuberoinfundibulum of the arcuate nucleus. Prolactin release from lactotrope cells in the anterior pituitary is under inhibitory control by dopamine; therefore the reduced dopamine caused by the opioids results in an increase in plasma prolactin. Prolactin counteracts the effects of dopamine, which is responsible for sexual arousal, and high levels of prolactin can result in impotence and loss of libido. Long-term opioid use can increase growth hormone by inhibiting somatostatin release; this regulates GH-releasing hormone secretion.⁵⁰

Antidiuretic hormone (ADH) and oxytocin are synthesized in the perikarya of the magnocellular neurons in the

**Figure 66-1** Opioid structures.

paraventricular and supraoptic nuclei of the hypothalamus and are released from the posterior pituitary. Kappa opioid receptor agonists inhibit the release of oxytocin and antidiuretic hormone (and cause prominent diuresis). MOR agonists have minimal effect or tend to produce antidiuretic effects in humans, and reduce oxytocin secretion.⁵¹ Some of the opioids (i.e., morphine) stimulate histamine release, resulting in hypotension and secondary ADH release. The effects of the opioids on vasopressin and oxytocin release may reflect both a direct effect upon terminal secretion and indirect effects upon dopaminergic and noradrenergic modulatory projections into the paraventricular and supraoptic hypothalamus.^{52,53}

Miosis

Lumination of the pupil activates a reflex arc, which, through local circuitry in the Edinger-Westphal nucleus, activates parasympathetic outflow through the ciliary ganglion to the pupil, producing constriction. The parasympathetic outflow is locally regulated by GABAergic interneurons, and the opiates are believed to block GABAergic interneuron-mediated inhibition, resulting in miosis.⁵⁴ At high doses of agonists, the miosis is marked, and pinpoint pupils suggest opioid intoxication. Although some tolerance to the miotic effect develops with therapeutic doses of the opioids, high circulating concentrations of opioids continue to result in constricted pupils.

Myoclonus and Seizure

Myoclonus and seizures have been reported in patients receiving high doses of opiates.^{55,56} In addition, seizure-like activity can occur with extremely high doses of the opioids. Seizures may also occur at lower doses of meperidine owing to the normeperidine metabolite, which lowers the seizure threshold. Myoclonus and seizure activity is thought to be due to inhibition of GABA from inhibitory interneurons in the hippocampal pyramidal cells and dorsal horn cells.⁵⁷ The opiates also have a direct stimulatory effect through interaction with G inhibitory and stimulatory coupled receptors.⁵⁸ It has been suggested that in addition to the normeperidine metabolite, which is seizurogenic, morphine-3-glucuronide (from morphine) may induce myoclonus and seizures at high doses.^{59,60}

Nausea and Vomiting

The gastrointestinal tract is under the control of the vomiting center located in the brain stem. The vomiting center is activated by the chemoreceptor trigger zone (CRTZ), the vestibular system, and the gastrointestinal tract. The opioids activate the CRTZ, sensitize the vestibular system, and reduce gastric emptying time, all of which will lead to activation of the vomiting center.⁶¹ Drugs that reduce CRTZ activity (antidopaminergics, 5-hydroxytryptamine₃ (5-HT₃) serotonin receptor antagonists) and vestibular sensitization (anticholinergics, antihistamines) will reduce opioid-induced nausea. Drugs that enhance gastrointestinal motility are also effective (e.g., metoclopramide).⁶²

Constipation

It is estimated that 40% to 95% of patients treated with opioids show constipation, and that changes in bowel function can be demonstrated even with acute dosing.⁶³ Opioid receptors are densely distributed in enteric neurons between the myenteric and submucosal plexuses and on a variety of secretory cells.^{64,65} Stimulation of MOR in the intestines reduces propulsive and diminishes intestinal secretions.⁶⁵ The prolonged transit time of the intestinal contents, along with reduced intestinal secretion, leads to increased water absorption, increasing the viscosity of bowel contents and constipation. In addition, anal sphincter tone is increased, and reflex relaxation in response to rectal distension is reduced. All of these effects combine to contribute to morphine-induced constipation.⁶⁶ Tolerance to opioid-induced constipation does not occur.

Biliary Spasm

Relaxation of the sphincter of Oddi is suppressed by the opioids, which can result in an increase in the common bile duct pressure, leading to symptoms of biliary colic. Therefore, treatment of the pain of biliary colic with the opioids can lead to an exacerbation of the pain rather than relief.

Urinary Retention

MOR agonists inhibit the urinary voiding reflex, increase the tone of the external sphincter, and induce bladder relaxation, which can result in urinary retention. This effect is mediated by MOR and delta-opioid receptor activation in the brain and spinal cord. This will result in higher bladder volumes and sometimes requires catheterization.⁶⁷

Pruritus

Pruritus can occur with all of the MOR agonists. The mechanism is thought to be due to disinhibition of itch-specific neurons, which have been identified in the spinal dorsal horn.⁶⁸ It can occur with both systemic and spinally administered doses but is more common with spinally administered doses.⁶⁹ It tends to be focused in the trunk and face.

Immunosuppression

The effect of the opioids on immune function is controversial. The opioids suppress immune function through a direct effect on immune system cells and indirectly by activating sympathetic outflow and modulation of the hypothalamic-pituitary-adrenal axis.^{70,71} A proposed mechanism for the immune suppressive effects of morphine on neutrophils is through nitric oxide-dependent inhibition of nuclear factor κ B (NF κ B) activation.⁷² Others have proposed that the induction and activation of mitogen-activated protein (MAP) kinase may play a role.⁷³ Pain itself is immunosuppressive; therefore, a reduction in pain will counteract and probably outweigh the direct immunosuppressive effects of the opioids. In addition, it appears that acute delivery of the opioids is more immunosuppressive than long-term delivery, suggesting tolerance to this effect.

Sweating

The opioids exert a wide range of effects on thermoregulation with high doses leading to hyperthermia and low doses leading to hypothermia.⁷⁴ Excessive sweating has been reported to occur in as many as 45% of patients taking methadone. The mechanism appears to be related to release of histamine.⁷⁵⁻⁷⁷

ANTIDEPRESSANTS

Antidepressants have long been used for the treatment of chronic pain. In the past, they were more often chosen to improve mood rather than to treat pain because of coexisting anxiety and depression. After separate studies showed improved pain control in patients without depression, as well as in patients with depression without improvement in mood, it was realized that these medications have independent analgesic actions.^{78,79} Further, improvement in pain is seen earlier and at lower doses than improvements in depression, also demonstrating this analgesic efficacy.⁸⁰ A recent meta-analysis of 18 randomized, placebo-controlled studies with multiple antidepressants concluded that there was strong evidence for efficacy of antidepressants for pain relief, fatigue, and sleep disturbance, and in improving health-related quality of life.⁸¹ The FDA in the United States has now approved selective SNRIs for fibromyalgia, diabetic peripheral neuropathy, and chronic musculoskeletal pain. Nevertheless, not all antidepressants are effective pain medications. For example, the SSRIs have minimal analgesic properties and therefore have a limited role in the treatment of chronic pain.⁸² Trazadone, used mainly for sleep, is another antidepressant without analgesic actions.

The main site of analgesic action is thought to be the reuptake inhibition of norepinephrine and serotonin at the level of the spinal cord and higher. This inhibition increases the extracellular concentration of these two monoamines, resulting in activation of descending inhibitory pain pathways, and ultimately decreases pain.^{83,84} A peripheral action

has also been proposed because topical antidepressants were shown to produce analgesia in animal models of pain.^{83,85} Current investigation has shown that topical application can result in the inhibition of NMDA receptors and the blockade of sodium and calcium channels, which alone or in combination could explain their peripheral analgesic properties.^{83,86-88} Because TCAs are effective in blocking sodium channels, and the proliferation of sodium channels plays a key role in the pathogenesis of neuropathic pain, this may be one of the main sites of action for these drugs.^{89,90} Finally, TCAs have been shown to potentiate endogenous opioids⁹¹ (Figure 66-2).

Tricyclic Antidepressants

TCAs are considered first-line agents in the treatment of chronic neuropathic pain and fibromyalgia.^{92,93} Two systematic reviews with 17 randomized controlled trials (RCTs) using 10 antidepressants have shown numbers needed to treat (NNTs) of approximately 2.5 for neuropathic pain (Table 66-5).^{94,95} All TCAs have shown fairly equal efficacy within the class.

TCAs are usually divided into tertiary amines (amitriptyline, imipramine, and doxepin) and secondary amines (nortriptyline and desipramine). Nortriptyline and desipramine are demethylated in the liver from amitriptyline and imipramine, respectively. The tertiary amines tend to block the reuptake of serotonin more than norepinephrine, and the secondary amines are more selective in their inhibition of norepinephrine uptake.

It is recommended that tricyclics should be started at the lowest dose possible and titrated slowly. A typical starting dose for amitriptyline, nortriptyline, or desipramine is as low as 5 to 10 mg before bedtime. Doses can be increased by the same amount as the starting dose approximately every 7 days (Table 66-6). Studies have shown improved analgesia with amitriptyline in the range of 25 to 50 mg, but some studies have gone as high as 200 mg. Response should be seen within 3 to 4 weeks (see Table 66-6).

Table 66-5 Analgesic Efficacy of Antidepressants

Antidepressant	Animal ^a		Humans ^b	
	Number of Studies	Positive Results	Number of Studies	Combined NNT ^c
TCAs	126	Acute pain tests 81% Chronic pain models 95%	23	3.1
SSRIs ^d	39	Acute pain tests 44% Chronic pain models 33%	3	6.8
SNRIs ^e	10	Acute pain tests 100% Chronic pain models 100%	3	5.5
Others ^f	7	Acute pain tests 100% Chronic pain models 100%	1	1.6 (bupropion: only one study)

^aData adapted from Eschaler A, Ardid D, Dubray C: Tricyclic and other antidepressants as analgesics. In Sawynok J, Cowan A, editors: *Novel aspects of pain management: opioids and beyond*, New York, 1999, Wiley-Liss, pp 303–310; and Sawynok J, Cowan A: *Novel aspects of pain management: opioids and beyond*, New York, 1999, Wiley-Liss, pp 303–310. Complete up to 2005. Only approximately 10% of the animals were treated using chronic pain models.

Figure 66-2 Chemical structures of antidepressants.

Side Effects

Unfortunately, side effects with all of the TCAs are common and can limit use, especially in the elderly and in patients with hepatic impairment. Side effects tend to be less with the secondary amines. Sedation is common owing to its antihistamine effects but can be beneficial if there are sleep complaints. Anticholinergic side effects, which include dry mouth, constipation, urinary retention, and blurred vision, are also prevalent. Both anticholinergic and antihistamine side effects are dose dependent and can decrease with time; slow titration can improve compliance. Weight gain and sexual dysfunction are frequently reported. Cardiac side effects include orthostatic hypotension and **dysrhythmias**. Cardiac history should be reviewed and a baseline electrocardiogram (ECG) should be considered for patients over the age of 40. Seizure thresholds are lowered. Risk of suicidal thinking and behavior is increased in children, adolescents,

and young adults up to the age of 24. Further, if these medications are taken intentionally or accidentally in overdose, they are dangerous and can be extremely lethal at relatively low doses. When these medications are stopped, it is recommended that they be reduced by 25% per week to decrease side effects.

Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)

The SNRIs, venlafaxine, duloxetine, and milnacipran, have also shown analgesic properties. Together they have shown benefit in painful diabetic peripheral neuropathy, neuropathic pain, fibromyalgia, and, most recently, chronic musculoskeletal pain. Venlafaxine, the first drug in this class, is an inhibitor of serotonin reuptake at low doses, and at higher doses it inhibits norepinephrine reuptake. This means that it acts more like an SSRI at lower doses and

Table 66-6 Tricyclic Antidepressants: Pharmacodynamics

Drug	Amitriptyline	Desipramine*	Doxepin	Imipramine	Nortriptyline

does not become an SNRI until higher doses, where more side effects occur. Venlafaxine has shown some effectiveness with polyneuropathy,⁹⁶ including painful diabetic neuropathy⁹⁷ and fibromyalgia, but all of these indications are off-label.⁹⁸ Doses range from 75 to 225 mg/day. Milnacipran has been approved for use in fibromyalgia in the United States but not in Europe. A recent meta-analysis using five studies (4129 patients) showed that this drug was superior to placebo except for sleep disturbance in treating fibromyalgia.⁹⁹ Doses ranged from 25 to 200 mg/day. This same paper found four duloxetine studies (1411 patients) showing superiority to placebo in fibromyalgia except for fatigue symptoms.⁹⁹ Long-term benefit of 6 months has been shown with single daily doses of 60 or 120 mg per day of duloxetine for fibromyalgia. Starting doses are 20 to 30 mg in the morning. Duloxetine has also been approved for diabetic peripheral neuropathy in the United States. It has been shown to be superior to placebo at doses between 60 and 120 mg per day with this disorder, and patients typically respond within the first week.¹⁰⁰⁻¹⁰² Last, duloxetine has also shown efficacy in treating chronic musculoskeletal pain, including discomfort from osteoarthritis and chronic lower back pain.¹⁰³⁻¹⁰⁶

Side Effects

Side effects of all three of these SNRIs include nausea, dry mouth, and constipation. Sexual side effects tend to be less than with SSRIs. Duloxetine should not be used with coexisting hepatic insufficiency. Milnacipran is not recommended for patients with end-stage renal disease but is unique in that it is not metabolized by cytochrome P450 isoenzymes. Serotonin syndrome, caused by iatrogenic overstimulation of central and peripheral serotonin receptors, presents with neuromuscular hyperactivity, autonomic hyperactivity, and altered mental status. It may occur abruptly and progress rapidly when these drugs are used at

high doses or combined with other medications that stimulate serotonin. These drugs can also impair platelet aggregation, particularly if used concomitantly with aspirin or NSAIDs. Dose-related increases in blood pressure have been reported and should be followed. SNRIs carry a black box warning in the United States for increased risk of suicidal thinking and behavior in children, adolescents, and young adults under the age of 25. When these medications are discontinued, withdrawal symptoms have been reported. It is recommended that the dose be decreased by 25% per week to minimize these symptoms (see [Tables 66-3 and 66-5 through 66-9](#)).

ANTICONVULSANTS

Neuropathic pain (NeP) is chronic pain initiated by nervous system lesions or dysfunction and maintained by a number of mechanisms. Excess stimulation of nociceptive pathways or damage to non-nociceptive pathways alters the balance between painful and nonpainful inputs so that pain results without nociceptor stimulation. Several cellular and molecular mechanisms operating over different periods of time are thought to be involved in the abnormal peripheral and central nervous system activity associated with NeP.¹⁰⁷ Many of these mechanisms can be modulated by the anti-convulsants. First, nerve injury is reported to evoke spontaneous discharges from the cell bodies of myelinated fibers at the levels of the dorsal root ganglia. The mechanism of spontaneous activity is thought to be secondary to an increase in concentration of sodium channels in neuromas, dorsal root ganglion cells, and areas of demyelination.¹⁰⁸ Second, spinal inhibitory interneurons modulate the peripheral-to-central transmission of pain signals, thus “gating” ascending sensory information.¹⁰⁹ GABA and glycine and their receptors are abundant in the superficial

dorsal horn,^{110,111} but their levels are regulated by primary afferent input and change significantly after nerve injury.¹¹¹

Finally, increased glutamatergic neurotransmission may also contribute to hyperexcitability and NeP through activation of both NMDA receptors and non-NMDA amino-3-hydroxy-5-methylisoxazole propionic acid (AMPA)/kainate-type glutamate receptors.¹¹² Therefore, drugs that modulate sodium channels, increase GABA, reduce glutamate release, or block glutamate effects can potentially reduce neuropathic pain.

The four main mechanisms of action of the anticonvulsants that result in pain reduction include (1) calcium channel modulation, (2) sodium channel blockade, (3) NMDA antagonism, and (4) GABA_A agonism. The net result of the mechanisms of action consists of reduced spontaneous pain and hypersensitivity through membrane stabilization, reduced neurotransmitter release, and reduced postsynaptic cellular activation in the dorsal horn of the spinal cord. Table 66-10 summarizes the mechanisms of action of the various anticonvulsants.

With the exception of pregabalin and gabapentin, studies on the efficacy of the various anticonvulsants to treat pain have been inconsistent. Pregabalin is FDA approved to treat postherpetic neuralgia (PHN), painful diabetic peripheral neuropathy (DPN), and fibromyalgia; gabapentin is FDA approved to treat PHN; carbamazepine is FDA approved to treat trigeminal neuralgia; and valproic acid and topiramate are FDA approved to treat migraine headaches. The discussion in this chapter will focus on pregaba-

lin and gabapentin, which have the most evidence in support of treating chronic neuropathic pain (Table 66-11).

Mechanism of Action

Pregabalin and gabapentin are synthetic molecules that are structurally related to GABA. Both structures are derived

by the addition of a cyclohexyl or branched-chain aliphatic carbohydrate moiety to the GABA backbone. However, the three-dimensional shapes of pregabalin and gabapentin are significantly different from GABA. The amine (NH_2) and carboxyl groups (CO_2H) are closer to each other than in the native GABA structure. It is proposed that this difference in the three-dimensional structure of pregabalin and gabapentin versus GABA accounts for their different pharmacologic activities.^{113,114}

Although the exact mechanism of action of gabapentin and pregabalin is unknown, results from animal models suggest that pregabalin modulates neuronal hyperexcitability, resulting in analgesic and anticonvulsant effects. Reduction of neurotransmitter release occurs because pregabalin selectively binds to the $\alpha_2\text{-}\delta$ subunit of the N and P/Q subtypes of calcium channels of neurons in the brain and spinal cord, thereby modulating calcium influx into presynaptic cells.¹¹⁵ Therefore, there is less postsynaptic activation

through the AMPA/kainate, NMDA, and neurokinin receptors. Unlike the opioids, which limit calcium influx via a G protein pathway, no tolerance is associated with pregabalin and gabapentin. Gabapentin and pregabalin do not have any effect on L-type calcium channels (e.g., verapamil); therefore, there is no effect on blood pressure.

Pharmacology of Gabapentin and Pregabalin

Gabapentin

Gabapentin has a nonlinear bioavailability with a reduction in absorption as the dose increases. This is the result of an active and saturable transport mechanism.¹¹⁶ Gabapentin 900 mg has 60% bioavailability, and a 3600-mg dose has only 33% bioavailability. More frequent delivery of smaller doses may improve bioavailability through the saturable transport mechanism. It is less than 3% protein bound, and because of its high lipid solubility, it readily penetrates the CNS. Gabapentin is not metabolized and is excreted unchanged in the urine. Therefore, renal impairment will significantly increase the drug half-life. Studies have shown efficacy at doses up to 1800 mg and 2400 mg; however, doses above 1800 mg/day do not appear to be more efficacious, and the current maximum FDA-approved dose to treat pain is 1800 mg/day. Because of its nonlinear kinetics, titration of gabapentin to an effective dose can be prolonged with an average onset of 10 to 14 days after initiation.

Pregabalin

Pregabalin is not dependent on active transport for absorption and therefore has linear kinetics with bioavailability of about 90%. Unlike gabapentin, pregabalin absorption is independent of dose. It has negligible protein binding and readily penetrates into the central nervous system. Pregabalin is not metabolized and is excreted unchanged in the urine; therefore, renal impairment will significantly increase the drug half-life, and dose adjustments are required.¹¹³ The effective dose of pregabalin is between 150 and 300 mg per day. Owing to the linear kinetics and high bioavailability, the effective dose can be achieved in 2 to 3 days; therefore, onset is faster than with gabapentin.

Toxicity of Gabapentin and Pregabalin

Neither gabapentin nor pregabalin has any significant drug interactions, and protein binding is minimal. Because gabapentin and pregabalin have similar mechanisms of action, their side effect profiles are very similar. The most common side effects with at least more than twice the incidence of placebo in controlled trials were dizziness, somnolence, dry mouth, peripheral edema, blurred vision, weight gain, and thinking abnormalities. Dizziness and somnolence usually began shortly after initiation of therapy, and most cases resolved with continued dosing. Dizziness and somnolence are dose related and can be reduced with slow titration. This side effect can also be an advantage when administered at night in that it will improve sleep. Controlled studies with gabapentin and pregabalin have demonstrated improved sleep quality when compared with placebo.^{1,2} Xerostomia (dry mouth) is dose dependent; however, it is usually mild,

Table 66-11 Comparison of Gabapentin and Pregabalin Pharmacology

Schedule	Unscheduled	Schedule V

FDA, U.S. Food and Drug Administration.

Figure 66-3 Chemical structures of pregabalin and gabapentin.

and few withdrawals from clinical trials have resulted from this side effect. Peripheral edema occurred in almost a third of subjects in clinical trials. It does not appear to be dose related, nor is it associated with any cardiovascular, renal, or hepatic abnormalities. It is more common with the concomitant use of a thiazolidinedione antidiabetic agent.¹¹⁷ Blurred vision is dose related and usually resolves with continued use. It is not associated with any ocular abnormalities. Weight gain has been reported to be as high as 8% of baseline weight but is not associated with any cardiac, renal, or hepatic abnormalities. A mildly increased appetite was reported in epilepsy and fibromyalgia trials. There is no association with baseline body mass index (BMI), gender, or age. Weight gain appears to plateau and is mild. Thinking abnormalities are typical of anticonvulsants and are consistent with the calcium channel modulation mechanism of these agents. Thinking abnormalities tend to be mild but can be bothersome enough in some patients to lead to discontinuation.

Anticonvulsants, including gabapentin and pregabalin, have approximately twice the risk of suicidal ideation over placebo. This increased risk is not age related and appears to occur at between 1 and 24 weeks of therapy. Patients should be warned of this side effect and instructed to contact their health care provider immediately if it occurs.

Studies with pregabalin have shown a mild PR interval prolongation that was not associated with increased risk of second- or third-degree atrioventricular block. Pregabalin may result in a mildly decreased platelet count, which is not associated with an increase in bleeding-related adverse events. Pregabalin may also result in mild elevations in creatinine kinase, which are asymptomatic in most patients.

In controlled clinical trials of pregabalin, more patients reported euphoria as compared with placebo. In a follow-up drug likability study in recreational drug users of sedative-hypnotics, pregabalin subjects reported a “good drug effect,” “high,” and “liking” to a degree that was similar to 30 mg of diazepam. In addition, clinical studies showed withdrawal symptoms of insomnia, nausea, headache, and diarrhea. Therefore, the FDA approved the drug with a category V controlled substance schedule. Although pregabalin is Schedule V, it has very low abuse potential. As with any anticonvulsant therapy, pregabalin and gabapentin should be withdrawn slowly over at least a week to avoid withdrawal symptoms (Figure 66-3).

MUSCLE RELAXANTS

Patients frequently describe muscular pain as “spasms,” and clinicians clearly know that loss of range of motion is

detrimental to their patients. It makes sense that a medicine that acts as a “muscle relaxant” would be of great value in treating patients with these complaints. Unfortunately, skeletal muscle relaxants do not have a primary role in the treatment of chronic pain because of limited true effects on muscles, significant side effect profiles, drug interactions, or addiction potential.

The list of medications classified as skeletal muscle relaxants is highly diverse (Figure 66-4). Because each of the drugs in this class has a unique mechanism of action and side effect profile, each medication from this class must be examined separately. Adding to the difficulty of understanding these medications is the lack of consensus as to how or why they provide benefit. The two approved clinical indications are for treatment in upper motor neuron diseases that result in spasticity and in peripheral musculoskeletal disorders that cause pain and spasms. Each of these medications can thus be classified as an antispastic or antispasmodic agent. These medications should not be used as first-line medications and usually should be used in conjunction with other pain medications. In addition, most antispasmodic medications come with restriction of use to 2 to 3 weeks. Despite this, many skeletal muscle relaxants are prescribed on a long-term basis for chronic conditions.¹¹⁸

Understanding the reflex arc in muscle is important in understanding where these agents act. The simplest reflex is monosynaptic. A muscle spindle transmits an efferent signal through the Ia afferent neuron; this enters the dorsal horn of the spinal cord and synapses on an alpha motoneuron. This neuron then exits the spinal cord through the ventral root and innervates the extrafusal fibers of the same muscle, causing a contraction in the muscle. The Ia afferent signal is also transmitted polysynaptically through interneurons that inhibit alpha motoneurons of antagonist muscles, causing them to relax. Gamma motoneurons located in the ventral horn adjust the sensitivity of the muscle spindles to stretch. They travel with the alpha motoneurons and receive input from cutaneous receptors and many supraspinal pathways, including the corticospinal and reticulospinal tracts. Polysynaptic spinal reflexes with supraspinal connections are much more abundant than monosynaptic reflexes. These connections are both excitatory and inhibitory, providing improved control and feedback to set and fine-tune motor tone. The main tract that inhibits spinal reflexes is the dorsal reticulospinal tract, and the main excitatory pathway is the bulbopontine tegmentum.¹¹⁹

Spasticity occurs in upper motoneuron disorders such as multiple sclerosis, spinal cord injuries, traumatic brain injuries, strokes, and cerebral palsy. These diseases cause loss of descending inhibition from the brain to the spinal cord, leading to muscular hypertonicity and increased resistance to stretch. This presentation, which is classically described as a “clasp-knife phenomenon,” tends to affect the flexors of the upper extremities and the extensors of the lower extremities more than other muscle groups. Medications approved for spasticity include baclofen (Lioresal), dantrolene (Dantrium), tizanidine (Zanaflex), and diazepam (Valium).

The antispasmodic agents are used to treat muscle pain and spasms when hypertonicity, hyperreflexia, or other signs of upper motoneuron disorders are not present. This presentation is much more common than spasticity and

Figure 66-4 Chemical structures of muscle relaxants.

would include syndromes such as fibromyalgia, tension headaches, myofascial pain disorders, and nonspecific back pain. Medications include cyclobenzaprine (Flexeril), carisoprodol (Soma), metaxalone (Skelaxin), chlorzoxazone (Parafon Forte), methocarbamol (Robaxin), and orphenadrine (Norflex). Tizanidine and benzodiazepines are approved for both spasticity and musculoskeletal disorders. How each of these drugs improves these conditions is not completely clear, but the nonspecific sedative effects may have greater importance than the effects on muscles or spinal reflexes.

Antispasmodic Medications

Baclofen

Baclofen blocks presynaptic and postsynaptic GABA_B receptors^{120,121} and disrupts polysynaptic and monosynaptic reflexes at the spinal cord level.¹²² Oral doses usually start at 5 mg three times per day with a maximum dose of 80 mg per day. This medication frequently can be used intrathecally for the same indication with a reduction in clinical side effects. Sedation, weakness, hypotension, nausea, depression, and constipation have been reported. Taper slowly and adjust for renal impairment. Withdrawal symptoms include hallucinations, seizures, and pruritus.

Dantrolene

Dantrolene acts directly on the muscle by decreasing the release of calcium from skeletal muscle sarcoplasmic

reticulum.¹²³ It has a black box warning about hepatotoxicity.¹²⁴ Its risk is much greater with patients taking 800 mg per day or more compared with doses of 400 mg per day. It is recommended to stop this medication after 45 days if no benefit is derived.

Tizanidine

Tizanidine is a centrally acting agonist of the α_2 receptor,^{125,126} which reduces the release of excitatory amino acids from the presynaptic terminal of spinal interneurons.¹²⁷ This reduces tonic stretch reflexes and polysynaptic reflex activity.¹²⁸ Doses start at 2 to 4 mg at night and increase by 2 to 4 mg three to four times per day with a maximum dose of 36 mg per day. Side effects include hypotension, sedation, and dry mouth. Its major route of elimination is renal, and renal impairment can significantly decrease clearance. It is metabolized via CYP1A2, and concomitant use with ciprofloxacin or fluvoxamine is contraindicated.¹²⁹ Elevated liver functions—three times the upper level of normal—have occurred in 5% of patients.¹²⁹ Monitoring of liver function is recommended. Acute withdrawal can cause hypertension, tachycardia, and hypertonia. Use with alcohol should be warned against, and oral contraceptives will decrease clearance with doses as low as 4 mg per day.

Diazepam

Diazepam works by central blockade of GABA_A,^{123,130} which is an inhibitory neurotransmitter in the central nervous

system. It was the first drug used to treat spasticity and is often used to compare new agents in clinical trials. Efficacy for spasticity and muscle pain is believed to be similar to that of benzodiazepines as a class.¹³¹ Clinical trials showing efficacy with benzodiazepines are based on tetrazepam, which currently is not available in the United States.¹³² It is not considered a first-line agent for spasticity or muscle pain because of its sedative effects, drug interactions, and significant abuse potential.

Antispasmodic Medications

Cyclobenzaprine

Cyclobenzaprine is structurally related to tricyclic antidepressants and thus causes sedation through its anticholinergic effects. It acts primarily at the brain stem to reduce tonic somatic motor activity influencing both gamma and alpha motoneurons. Dosing at 5 mg three times per day has shown similar efficacy when compared with 10 mg three times per day with reduced side effects.¹³³ The maximum daily dose is 30 mg. This medication also comes in 15- and 30-mg extended-release formulations. Concomitant use with MAO inhibitors is contraindicated. This drug should not be used during the acute recovery phase of myocardial infarction, or in patients with arrhythmias, heart block, congestive heart failure, or hyperthyroidism. The risk of seizures with tramadol is increased if this medication is added.¹³⁴ The risk of serotonin syndrome can be increased in patients taking selective serotonin reuptake inhibitors.¹³⁵

Carisoprodol

Carisoprodol in animal studies has shown muscle relaxation through altered interneuronal activity in the spinal cord and in the descending reticular formation of the brain. It is metabolized in the liver to meprobamate, a Schedule IV medication with abuse potential.¹³⁶ Meprobamate binds to GABA_A receptors, which results in further sedation. Doses start at 250 mg up to four times per day with a maximum dose of 1400 mg per day. It is contraindicated in patients with a history of acute intermittent porphyria. CYP1C19 inhibitors such as omeprazole or fluvoxamine may increase carisoprodol levels and decrease meprobamate. CYP1C19 inducers such as rifampin or St. John's wort increase exposure to meprobamate.

Methocarbamol

Methocarbamol, a carbamate derivative of guaifenesin, is a central nervous system depressant with no direct action on striated muscle, the motor end plate, or the nerve fiber. It comes in 500- and 750-mg tablets and can be given up to four times per day with maximum dose of 8 g per day. The parenteral form has been associated with skin sloughing and thrombophlebitis. It should be used with caution in patients with myasthenia gravis receiving anticholinesterase agents.

Metaxalone

Metaxalone also has no direct actions on muscles. Its effects occur mainly through generalized central nervous system depression. It tends to cause much less sedation than other

drugs in this class and has limited drug interactions. It is contraindicated in drug-induced, hemolytic anemias and in significantly impaired renal or hepatic function. The dose most commonly used is 800 mg three or four times per day.

Chlorzoxazone

Chlorzoxazone is a centrally acting agent that acts primarily at the level of the spinal cord and subcortical areas of the brain, where it inhibits multisynaptic reflex arcs. Doses are 250 to 750 mg three or four times per day. Hepatocellular toxicity has been reported with this drug.

Orphenadrine

Orphenadrine is derived from diphenhydramine. It does not directly relax muscles and possesses greater anticholinergic properties than diphenhydramine. Its dosage recommendation is 100 mg twice a day. It is contraindicated in patients with glaucoma, pyloric or duodenal obstruction, stenosing peptic ulcers, prostatic hyperplasia or obstruction of the bladder neck, cardiospasm (megaesophagus), and myasthenia gravis.

Efficacy

Clinical studies using these drugs are very limited, poorly controlled, and of short duration. One meta-analysis¹³⁷ found fair evidence that tizanidine and baclofen are roughly equivalent and are similar to diazepam for the treatment of spasticity. Investigators go on to state that data on efficacy for muscle relaxants with musculoskeletal conditions are limited, but for treatment compared with placebo, cyclobenzaprine, tizanidine, carisoprodol, and orphenadrine showed a consistent trend favoring active treatment. Data demonstrating effectiveness for chlorzoxazone, methocarbamol, baclofen, and dantrolene are limited. Last, data for metaxalone are mixed.

EMERGING TARGETS

Nerve Growth Factor Inhibitors

Nerve growth factor (NGF) is a ligand to the tyrosine kinase (TrKA) receptor located on sensory neurons. Inflammation results in increased levels of NGF, which stimulate the TrKA receptor leading to an increase in inflammatory mediators and increased sensitivity to pain. Overexpression of NGF also leads to a proliferation of sympathetic fibers, which may be important in the production of inflammatory and neuropathic pain. Because NGF is essential for the survival and development of sensory neurons, NGF inhibitors may lead to peripheral nerve dysfunction and neuropathies. Tanezumab, a recombinant humanized monoclonal antibody targeting NGF, is in phase II trials and is being developed to treat pain associated with osteoarthritis, low back pain, and metastatic bone cancer.¹³⁸

Cannabinoid Agonists

Cannabinoid receptors type 1 (CB1) are located at multiple locations in the peripheral and central nervous system,

whereas CB2 receptors are located on inflammatory cells (monocytes, B/T cells, mast cells). CB2 activation results in a reduction in inflammatory mediator release, plasma extravasation, and sensory terminal sensitization. Activation of peripheral CB1 receptors results in a reduction in the release of proinflammatory terminal peptides and a reduction in terminal sensitivity. Activation of central CB1 receptors leads to reduced dorsal horn excitability and activates descending inhibitory pathways in the brain. The net result is a reduction in both pain and hyperalgesia. Inhaled cannabis has been extensively studied in various pain syndromes with mixed results. More recent well-controlled trials have shown promise.¹³⁹ Stativex is a sublingual spray containing a mixture of tetrahydrocannabinol and cannabidiol, which is currently in phase II trials for the treatment of cancer-related pain. It has been shown to reduce the pain of rheumatoid arthritis and chronic pain of various other causes.^{140,141}

AMPA/Kainate Antagonists

Glutamate, an excitatory amino acid neurotransmitter, has been implicated in pain perception. Two types of glutamate receptors are found in the central nervous system: ionotropic and metabotropic. Ionotropic receptors are further functionally categorized into NMDA and non-NMDA receptor subtypes (AMPA and kainate receptors).¹⁴² AMPA and kainate receptors are prevalent within the dorsal horn of the spinal cord, and activation is thought to mediate rapid excitatory neurotransmission, resulting in central sensitization mechanisms. Tezampanel, an intravenously administered antagonist of AMPA and kainate receptors, has been shown to be effective in reducing human experimental pain.¹⁴³ NGX426, an oral prodrug of tezampanel, is in clinical development.

KEY POINTS

Treatment of unrecognized depression is probably the psychosocial intervention with the greatest impact and is frequently required.

Matching reading level of patient education material to that of the patient is an important consideration.

Improvement in physician-patient communication can be facilitated by specific actions, such as asking the patient to write down concerns in preparation for each visit or to repeat back what he or she has learned.

Anything that contributes to the physician's understanding of the patient's experience can be extremely important.

Any increment in appreciation of the experience of illness from the patient's point of view does the most to complement the complete range of psychosocial, rehabilitation, medical, and surgical interventions. Perhaps the most important tested psychosocial intervention is recognition of, and conventional treatment of, concomitant depression. Other tested psychosocial interventions—interviewing techniques, improvement in physician-patient communication, and disease-specific patient education efforts—tend to revolve around patient education aimed at the right reading level.^{1,2}

ILLNESS EXPERIENCE IN RHEUMATIC DISEASE

Pain

What the illness means to the patient is difficult to grasp. Reading what patients have written about arthritis is not the same as having arthritis; listening and talking and teaching are not the same as having the experience. Physicians who have become patients note in retrospect that the “illness experience” was much more complex than anticipated. The thing that seems to contribute most to making the experience of rheumatic diseases different from that of other medical and surgical conditions is the combination of pain with chronicity.

“Since the pain never goes away, the emotions never go away. So it's a matter of finding out how to escape from the emotions. That's what gets to you; it's like a bloodhound pursuing you. They say, ‘Most patients feel somewhat better in 6 to 8 weeks.’ Six to 8 weeks feels like an eternity, and there's nothing left to do, nowhere to go.”

—50-year-old woman with rheumatoid arthritis (RA) of 10 years' duration and treatment with five different disease-modifying antirheumatic drugs.

Psychosocial Management of Rheumatic Diseases

W. NEAL ROBERTS, JR.

The average course of rheumatoid arthritis (RA) is about 27 years. The usual psychological defenses wear out. The illness becomes integrated, an unwelcome but integrated part of the individual.

“I used to believe that ‘my arthritis’ was separate from myself. I have come to understand, after 30 years of living with JRA [juvenile RA], that this is no less a part of me than my fingers, my voice. My appreciation for pain, especially that which goes unseen, for recognizing the reality of potential (not everyone can be whatever they want), and for the ability to work at accepting one's limitations has guided and still guides my perspective. Everything about who I am is wrapped in and around this illness.”

—Woman with juvenile RA since age 6

Additional Effects of Chronicity

Equal to pain for many patients is the loss of control and self-confidence that comes with chronicity.

“But when my symptoms are present, my self-image changes—I am aging, tentative, dependent, tinged with self-pity and regret. I am more willing to accept, rather than strive. In short, my confidence in my life and myself is reduced by how I feel physically. Despite this, a part of me rebels against this lowered self-esteem. It effectively refuses to accept the disease, to admit to not being able to do the things I once did with ease or even skill. These two conflicting personae—the hesitant reflective sick person and the unaccepting person who does what he wants despite how he feels—arise from each other in an uninterrupted, shifting pattern. Self-pity, which is the last stage of my sick person, awakens my healthy person. When he is eventually confronted with a task, however mundane, that symptoms prevent him from doing, the sick person reemerges, and the cycle begins anew.”

—Man with ankylosing spondylitis of 20 years' duration

Initial events of chronic pain and loss of control and confidence give rise to reactions and adaptations analogous to stages of reactions to acute losses in general—anger, denial, anxiety, and resignation. Management of these reactions and adaptations in the chronic setting may represent new problems of their own from the patient's point of view, depending particularly on the responses of the patient's social support system (family, friends, co-workers). Above all, during this series of emotional events, there is the possibility of the existence of treatable depression.

“Any patient with RA who tells you they haven't ever been depressed is lying. When I see those questionnaires about depression, I just mark something in the middle of the scale. It's embarrassing to admit how bad you feel.”

—50-year-old registered nurse with RA of 10 years' duration

FOUR LANDMARKS OF PSYCHOSOCIAL ADAPTATION IN RHEUMATIC DISEASES

Virtually every rheumatology patient faces four landmark events or processes that routinely require some active management: (1) the initial ambiguity of not getting a diagnosis, (2) getting a diagnosis and the denial that comes with it, (3) repeatedly struggling to understand risks and benefits, and (4) dealing with the impact of the disease on relationships with others. Everyone either receives a diagnosis or does not receive one. If there is no immediate diagnosis, it may help to realize that such ambiguity is a good prognostic factor. If the diagnosis is clinically and serologically obvious, the prognosis may be poor. When a clear diagnosis is made, it entails the patient overcoming denial and facing the fact of having a chronic illness. Subsequently, the risk-benefit decisions about therapies are ongoing. The disease changes; decisions have to be made again.

Family Relationships

Of these four landmark situations that almost every rheumatology patient encounters—facing the diagnosis of a chronic disease or the uncertainty of no diagnosis, understanding repetitive cost-benefit decisions and threats to family relationships—the last uses the most psychological capital. Helpful data in this fourth landmark area are available, but no template approach is known, especially when the patient is a child. In the latter case, the re-establishment of a peer group, through school, camp, or any other setting, is a primary goal (see Chapter 107). Despite the loss of self-confidence and the effects of pain, fatigue, and deformity, individuals with RA have the same divorce rate as the general population. RA patients have fivefold less remarriage if divorced, however.³ The rate of progression of disability in married patients is substantially less than for patients who are unmarried.⁴ Healthy husbands of wives with RA are affected by the realization of the vulnerability of their own health.⁵ Marriage increases social support and is a favorable psychosocial variable. RA is experienced in an interpersonal context that can be hard to understand. In couples, if the woman has RA that she perceives as severe, she is helped by congruent beliefs in the spouse. However, if the wife's emotional response to the RA is high, she is helped by fewer congruent emotions on the part of the husband.⁶ Childhood and adolescence are particularly unfortunate times to encounter rheumatic disease.⁷

The physician and the health care system can enable social support to some degree. From studies in systemic lupus erythematosus (SLE), it seems that such enabling effort has the greatest effect among patients who already have strong families, higher incomes, and low disease activity.⁸

FATIGUE

Fatigue in rheumatic diseases seems to be a complex admixture of effects of circulating cytokines presumably mediated by binding to receptors within the periaqueductal gray matter (reticular activating system) of the brain stem, deconditioning, and depression. These factors appear in differing proportions in different diseases. Fatigue is the most common chief complaint of patients with SLE.⁹ For patients

with RA, fatigue is prevalent,¹⁰ correlated with depression when that occurs,¹¹ and is the focus of elaborate coping strategies.¹² The pathophysiology of chronic widespread pain, despite the lack of obvious inflammation clinically, includes a contribution from cytokine-related fatigue. Patients with chronic widespread pain have reduced levels of anti-inflammatory cytokines interleukin-4 and interleukin-10.¹³ The rapid time course of the dramatic response of RA fatigue to tumor necrosis factor blockade—less than 1 week in some patients—shows that in many RA patients, fatigue must be due to circulating cytokines directly, rather than to deconditioning and psychological factors, which would not be expected to improve so rapidly.

In these patients, an anti-tumor necrosis factor agent essentially turns RA fatigue into SLE fatigue, which apparently is predominantly due to deconditioning and psychological factors. Maximum oxygen consumption for patients with RA is comparable with that of patients with SLE (slightly >50%). In contrast to RA, in SLE there is no association between fatigue and disease activity, or markers of inflammation. Unless cytokines are acting locally within the central nervous system with no concentration in serum, psychosocial factors may be a predominant cause of lupus fatigue.¹⁴ This mechanistic explanation begs the question of whether or not depression in SLE might be due to tonically elevated (or decreased) cytokines that do not vary much with disease activities. Transforming growth factor- β is an example of the latter type of cytokine elevation in SLE.

Another key reason for fatigue is treatable deconditioning. When 93 patients with SLE were compared with 44 sedentary controls, the patients were about 20% worse off with regard to muscular strength, forced expiratory volume, and maximum oxygen consumption. A smaller interventional study of exercise physiology preceded this one and found the same baseline.¹⁵ Patients were selected or pretreated to suppress SLE disease activity and underwent 8 weeks of aerobic conditioning, which was successful in reducing their fatigue by about half. A stepwise regression model explaining 37% of variation in SLE fatigue featured abnormal illness-related behaviors, greater age, greater degree of helplessness, and lack of health insurance as potentially responsible psychosocial variables.⁹

DEPRESSION

Diagnosable psychiatric disorders occur no more frequently in patients with rheumatic diseases than in patients with any other chronic disease. Two exceptions stand out statistically. First, patients with SLE have cognitive deficits, particularly as related to learning new things. Mild cognitive deficits, such as word finding difficulty,¹⁶ are prominent. Second, patients with widespread, nonarticular, axial aching have more diagnosable psychiatric illness—usually depression or anxiety—and are more likely to somatize. Patients across the spectrum of those usually seen in office practice rheumatology were compared in an attempt to map out the relationship between pain, disability, and abnormal psychology across diagnostic groups.¹⁷ The highest pain scores and the greatest psychological distress were reported by patients with axial disorders such as fibromyalgia, back pain, and neck pain. Patients with serious peripheral joint disease from RA had the most disability but the least pain and the

most normal psychological test scores. As a rule, patients with RA psychologically adapt over time and usually are as well adjusted and productive as their anatomy allows.¹⁸

Rheumatoid Arthritis

Most patients with moderately severe RA have been depressed. In a preliminary review of veterans' diagnoses ($n = 8706$ patients with RA), depression was more prevalent in RA (odds ratio, 1.48), more so in women and African-Americans, and less in older patients. Patients are resilient, however, and they adapt. Even the distress accompanying chronic joint pain in RA, described earlier as the "illness experience," fails to lead to sustained, treatable clinical depression most of the time. In RA, depression is not more common than among other rheumatology office patients, and pain causes psychological distress rather than the other way around.¹⁹ To an extent, the mental health aspect of RA may run an unexpectedly independent course. In one recent trial of a high-value (biologic) intervention, the mental health scale on the Short Form (SF)-36 was the outcome least correlated with the Disease Activity Score (DAS)28 and the American College of Rheumatology 20% response criteria (ACR20), and the pain score was the best correlated.²⁰ However, the mind-body dichotomy is not a rigid Cartesian one in RA. Circulating cytokines can exacerbate depression, and interleukin (IL)-6 might be more important than tumor necrosis factor (TNF) or IL-1 in this regard.²¹ It remains possible, although unproven, that psychological stress could exacerbate rheumatoid arthritis via hormonal effects upon neuronal transmission.²² Conversely, a systematic review of 27 different trials of psychological interventions for RA concluded that these interventions do increase physical activity levels, which at least has the potential to favorably alter structure.²³

Knee Osteoarthritis

Self-reported knee pain in the United States has the highest prevalence among elderly individuals and non-Hispanic black women.²⁴ Only younger and less educated patients presenting with knee osteoarthritis are more likely to be depressed, however.²⁵ Multiple regression analysis of a study of a mixed Asian population in Singapore revealed numerous independent variables associated with better outcome—some biologic, some fixed psychosocial, and some potentially modifiable. Among the best functioning patients with knee osteoarthritis were not only patients with less pain and less radiographic severity, but also patients with better education and less feeling of helplessness ("learned helplessness").

Chronic Widespread Pain, Fibromyalgia, and Low Back Pain

Overall, population-based studies show patients with chronic, nonarticular, axial aching rheumatic syndromes to be the group most likely to have an underlying psychiatric diagnosis. It is usually a mood disorder, such as depression or anxiety. Somatization is an important causal factor, at least for chronic widespread pain ascertained at the community level. Arguably, fibromyalgia and chronic

widespread pain are physiologically distinct. These conditions nonetheless form part of the same differential diagnostic group of nonarticular, axial aching and may overlap in the survey or population-based studies most generalizable to office practice.

Chronic widespread pain among unselected general populations is associated with a 17% incidence of a psychiatric diagnosis in Australia²⁶; one-quarter of a community sample of similar patients in Manchester, United Kingdom, had a psychiatric diagnosis.²⁷ In the Manchester group, the odds ratio for having a psychiatric illness if accompanying self-reported chronic widespread pain was 4.9 (95% confidence interval, 2.6 to 9.5). In the Australian phone survey ($n = 17,545$), 18% of the population had widespread chronic pain, which interfered with the daily activity of two-thirds. Psychosocial markers statistically associated with widespread chronic pain included less education, less income, lack of health insurance, and unemployment and disability payments. The same strong ties to psychosocial factors distinguish low back pain manifesting as part of chronic widespread pain from low back pain by itself. Finally, in prospective studies, patients initially without generalized axial aching, but who somatize, have increased risk of developing chronic widespread pain later.

DISABILITY, EMPLOYMENT, AND ECONOMICS

Health-related quality of life is significantly associated with paid work even when disease severity and demographics are controlled for, and even when societal safety nets are robust.²⁸ Individual patients with RA lose 30% of their work capacity. Societal costs of RA in economic and employment terms have now been estimated accurately at \$19.3 billion in 2005 dollars, with the burden divided as follows between four main stakeholder groups: patients 28%; employers 33%; and families and government nearly equal at about 20% each. Less firm estimates of quality of life deterioration and mortality double the total cost.²⁹ A bit less than half of the cost of a biologic can be paid for by the indirect cost gain from increased labor force participation.³⁰ Psychosocial factors affect the course of rheumatic diseases, especially with regard to employment and disability, against the background of this societal, economic context.

The effects of psychological and social factors on the presentation of many important diseases have been studied. These illnesses include the most statistically and economically important of the rheumatic diseases—osteoarthritis, RA, and low back pain—and SLE and fibromyalgia, as partially described earlier. Likewise, the effects of these diseases upon employment have been described. For Germans nationwide, ages 20 to 59, who had more than a decade of disease duration, the rank order of risk of unemployment from various rheumatic diseases was, from highest to lowest, granulomatosis with polyangiitis (formerly Wegener's granulomatosis), rheumatoid arthritis, scleroderma, lupus, psoriatic arthritis, and ankylosing spondylitis. The largest differences were noted between better-off psoriatic and spondyloarthopathy groups and the others.³¹ In Canada, the long-term work disability rate in RA after 10 years of disease duration is somewhere between 32% and 50%.²⁷ Whether early interventions to prevent unemployment are worth the

expense depends on accounting assumptions about how closely interests of the paying agency are aligned with those of patients receiving the intervention.³² In RA, failure to respond within the first 6 months at least to the level of an ACR20 predicts job loss even when a large response (ACR50) comes later.³³ It is interesting to speculate on how much of this disproportionate impact of the first 6 months upon employment is due to downstream effects of biologic events unique to the first 6 months of clinical disease versus how much is due to early psychological adaptations.

After severity of RA, the top two determinants of RA work disability are the physical difficulty of the job and the educational level of the patient.³⁴ Beyond these first three powerful factors, some psychological factors are important. These include most prominently a feeling of helplessness and employer support.³⁵ One large difference has been noted between patients' and doctors' perceptions about continuation of employment with RA. This difference involves employer support, which providers tend to underweigh compared with the importance that patients ascribe to it.³⁶ Low employer support could be viewed as a modifiable risk factor and therefore a target of psychosocial intervention.

Disability Insurance

In understanding disability and communicating that understanding to patients, four different funds of knowledge are of special value: (1) detailed knowledge of the mechanics and criteria of Social Security disability insurance (SSDI) in the United States,³⁷ (2) cross-cultural comparisons, (3) an appreciation of the major criticism raised in critique of the logical assumptions underlying the current system,³⁸ and (4) knowledge of research results showing what determines disability in specific diseases. Achieving reasonable expectations on the part of the patient and less frustration for the provider and the patient are two attainable goals of disability management.

The mechanics of the U.S. SSDI system vary from state to state but are simple and easily summarized. Reforms have reduced the number of steps between the initial application and the administrative law judge level. At this level, as an example, the court is empowered to ask and answer the question of whether a skin lesion, joint symptoms, and cognitive deficits in a patient with SLE are equivalent in severity to a stroke or renal failure, the actual default criteria. The waiting period before final adjudication of the disability claim is now shorter but still varies from state to state in the United States. Opportunities for the applicant to introduce new medical facts after the initial application is submitted are diminishing, however. Therefore, completeness of data at the initial application has greater importance. The appeal level in the streamlined version of the SSDI process reviews the correctness of the decision but allows few new medical data to enter the picture during the review. The patient has less opportunity to buttress medical weak points in his or her case in response to feedback from the system. The algorithm for advocacy therefore encompasses three elements, in order: (1) accrue the greatest quantity of objective data as possible, whether or not they are clinically necessary, being especially careful to document radiographic changes in patients with RA or other inflammatory arthritis; (2) write details about limits in daily and work activities in the

notes before beginning correspondence about disability; and (3) begin the application using an attorney with steps 1 and 2 firmly in place.

An algorithm for employer-provided private disability insurance in the United States might be entirely different. This difference arises from answers to the questions of who pays what when the patient is on light duty, part-time accommodation, short-term disability, or long-term disability. Some employers prefer to push ambiguous cases onto a long-term disability account, which is insured, rather than carrying a less than 100% effective employee in a current budget. Such an assignment to long-term disability insurance (which might eventually run out) may impede the patient's ultimate return to full-time work at the same firm, however.

Cross-cultural comparisons offer little help to individual patients experiencing economic losses, which constitute the indirect costs of rheumatic diseases. Between 1983 (Netherlands) and 1996 (Australia), many countries passed a milestone, however, at which the absolute numbers of individuals drawing disability payments surpassed the official number of unemployed for the first time. The United States and the United Kingdom passed this marker around 1993. Over the three years 2000 to 2003, 1.8 million people claimed work disability benefits in the United States. Economists speculate that these numbers were then large enough to affect macroeconomic statistics on the workforce participation rate.³⁹ Economists also argue that political incentives to record low unemployment numbers and the personal incentives of more payments for disability than for unemployment favor continuation of this trend for as long as it is fiscally sustainable.

In the long term, this may mean that disability insurance will become more like unemployment insurance. Such a change would have to involve acknowledgment that disability and unemployment are related aspects of a single work problem, significantly greater incentives for employers to hire and promote disabled individuals, and new incentives for patients to avoid disability rolls in favor of remaining in the workforce. Regardless of the future, and of an individual patient's struggle to salvage income levels in the face of illness, insight into the relationship between unemployment and disability can help maintain a perspective without which the disability issue has great potential to split the therapeutic alliance between physician and patient.

The major philosophical underpinning of the current SSDI system is the assumption that the amount of disease determines the amount of work disability.³⁸ A necessary corollary is that the amount of disease is objectively quantifiable. From the rheumatologic standpoint, two things are wrong. First, pain is self-reported and, by definition, not objectively quantifiable. Second, and more important, psychosocial factors are stronger determinants of disability than disease factors in many cases. Examples of the latter situation have been studied in a range of illnesses as outlined subsequently.

In one multivariate analysis of knee osteoarthritis only, age, female sex, obesity, and severity of knee pain maintained independent effects ($P < .0009$). All of these factors, individually and together, had greater influence on health assessment questionnaire-determined disability than did radiographic severity.⁴⁰ For 180 English patients with low

back pain,⁴¹ the best predictor of some pain persisting at 1 year of follow-up was concomitant widespread pain (odds ratio, 6.4). Other factors, from the most clinical, such as radicular pain, to the most psychological, such as job dissatisfaction, all showed equal odds ratios of about 3. Lack of influence over the work environment and poor social relations with co-workers⁴² are specific job-related factors influencing work disability from back pain.

Whiplash injury was definitively studied⁴³ in an experiment of nature when Saskatchewan switched from tort to no-fault auto insurance in 1995, abruptly disallowing claims for pain and suffering. Analysis of 7462 claims showed that the number and prognosis of neck injuries improved by about 30%. Depression influenced the duration of neck pain. The relative parity of psychosocial factors with clinical disease factors seen in the spine seems to be maintained in analyses of more peripheral musculoskeletal problems, such as forearm pain.⁴⁴ Patients with RA and patients with fibromyalgia report equal disability on a self-report scale, but patients with RA report less pain.

Labeling a patient with widespread pain or nonarticular axial aching as having fibromyalgia probably does not increase work impairment.⁴⁵ Disability awards for RA are heavily influenced by objective radiographic data—erosions and narrowing. Age, pain score, and depressed mood secondary to physical disability determine overall disability in RA, however, from the patient's point of view.⁴⁶ Fatigue plays a role in RA disability in that fatigue, more disability, more anxiety, and less social support all are correlated with one another in RA.⁴⁷ The odds are 2:1 to 3:1 against return to work for a patient with RA who stops working. SSDI, older age, and less education decrease the odds.⁴⁸ In SLE multivariate models for patients at university centers, predictors of early disability in the first 3 years included low educational level ($P = .0004$), a physical job ($P = .0028$), and disease activity at diagnosis ($P = .0078$). Cumulative organ damage and disease duration, race, and gender did not predict stopping work.⁴⁹

One randomized, unblinded trial of 13,077 Madrid⁵⁰ workers with temporary work disability in 1998 and 1999 showed a significant effect of an inexpensive, organized program. This program cut the incidence of long-term disability by half and saved about \$5 million using more frequent visits and patient education early on.

DETERMINANTS OF HEALTH CARE UTILIZATION AND DISPARITIES

Large Joint Osteoarthritis, Early Course

Depression seemed to influence younger patients and less well educated patients to seek attention for osteoarthritis of the hip or knee among a community interview sample of 108 patients older than 50 years. In this study,⁵¹ about half of the variance in the incidence of depression was explained by the effects or interactions of age, education, and self-assessment of osteoarthritis impact. Biologic and sociologic variables were analyzed together in a second community-based, much larger ($n = 1272$) survey study. Pain and other factors, none of which were modifiable psychosocial features, were independent influences on disability.⁵² Of several psychosocial variables affecting disability and usage, only

the psychological variable—depression in a younger patient—is amenable to direct intervention.

Large Joint Osteoarthritis, Late Course, Total Joint Arthroplasty

Later in the course of osteoarthritis, patient education, rather than detection and treatment of depression, may play the strongest role. In countering the effects of some sociologic factors important in selecting patients for total joint arthroplasty (TJA), specific defects in a patient's fund of knowledge can be targeted. African-American veterans have 10% higher Western Ontario and McMaster Universities Arthritis Index (WOMAC) scores in a multivariate regression model adjusting for severity.⁵³ Nevertheless, the subsets of African-Americans and older elderly patients tend to accept fewer arthroplasties. In a study of 596 older Cleveland veterans with symptomatic hip or knee osteoarthritis, African-American men in particular were only about half as likely (odds ratio, 0.50; 95% confidence interval, 0.30 to 0.84) to accept a recommendation for TJA. Underlying reasons for this racial disparity consist predominantly of expectations on the part of African-Americans of a more prolonged and troublesome postoperative period. African-Americans also were less familiar overall with TJA than were nonblacks.⁵⁴ Socioeconomic status per se has not been found to determine acceptance of TJA. In a Canadian survey of 48,218 people older than 55, 3307 had hip and knee problems verified as osteoarthritis by clinical examination and radiography. Individuals with the lowest socioeconomic status were equally willing to undergo TJA and needed it more than others, as might be expected from their lower educational attainment, leading perhaps to more physical occupations.⁵⁵

In-depth interviews of elderly patients reveal three common misconceptions influencing decisions about TJA. First, older patients expect that if their physician fails to make an explicit recommendation for TJA, this means they are not candidates. Patients believed that their provider was actively screening for the procedure, and that they had already been screened out. Second, elderly patients tend to believe that more pain and daily impairment are needed to make a favorable risk-benefit tradeoff than do orthopedic surgeons.⁵⁶ It has been suggested that this view is due partially to the fact that elderly patients are much more sensitive than their physicians to risk of mild postanesthesia cognitive deficits. Third is a philosophical difference: Elderly patients viewed osteoarthritis as normal aging to be tolerated, rather than as a disease to be operated on.

INFLUENCE OF READING AND EDUCATIONAL LEVELS

Generally, people with the lowest literacy have the worst health. Whether reading level per se carries an independent effect or is associated with other sociodemographic features such as poverty is uncertain.⁵⁷ A mechanism by which impaired literacy might have direct effects is clear enough, however. Patient information pamphlets, medication sheets, and other materials are written at reading levels too difficult for most American adults, putting a premium on

Table 67-1 Evidence-Based Psychosocial Interventions

Intervention	Target	Method	Results
Arthritis self-help/courses,* self-management programs	All arthritis diagnoses, fund of knowledge	4-12 hr of didactic sessions, trained leader, flip charts, overheads, handouts, discussion aimed at problem solving; pain, stress and depression management, medications, and communicating with providers	43% decrease in office visits over 4-yr follow-up; decreased pain satisfying criteria for clinical significance (15%-20% on visual analogue scale); increased exercise, increased fund of knowledge and self-efficacy; 9% decrease in disability ⁸⁴ ; most annual cost savings by patients with RA, \$162; sustained effect 4 yr after the intervention
Aquatics exercise, YMCA*	All arthritis diagnoses; range of motion, strength	12-30 hr over 6-10 wk; heated pool, lifeguard, trained instructor, physical therapist	13%-17% improvement in range of motion, strength in lower extremities, and self-efficacy; exercise compliance declines over time
Land-based exercise programs such as Arthritis Foundation PACE or walking programs	All arthritis diagnoses; range of motion, strength	Varies	Decreased depression and increased self-efficacy with respect to activities of daily living; decreasing adherence to exercise over time ⁸⁵
Phone follow-up of osteoarthritis	Symptomatic, radiographic knee osteoarthritis	Symptom monitoring phone call on a scheduled basis	Pain improvement similar in magnitude to that attained with an NSAID ⁸⁶

*Organized, current effort of Arthritis Foundation local chapters with certified instructor.

NSAID, nonsteroidal anti-inflammatory drug; PACE, People with Arthritis Can Exercise program; RA, rheumatoid arthritis.

non-literacy-dependent patient education. This persistent fact may be among the several reasons why face-to-face programs with groups of patients are particularly effective (Table 67-1).

The Internet promises to multiply the effects of reading and education and research,⁵⁸ but it may also contribute to a digital divide effect in the care of rheumatic diseases. On a theoretical basis, sociologic interventions touching on fundamental factors such as reading and education levels of the population as a whole might be expected to be the most effective psychosocial interventions for arthritis and rheumatic diseases and other diseases. It is logical that most proven psychosocial interventions consist of individual or small group provider-patient communications or patient education interventions that have the potential to overcome educational deficits and compensate for uncoordinated care (see Table 67-1).

Reading and education are complex psychosocial factors that may be associated with outcome through interaction with other variables as explanatory variables that help understanding, but offer poor targets for intervention; as epiphenomena rather than causes; and as carrier variables that are markers for other factors making the real contribution to outcome. The many abilities needed to gather and act on information used to participate actively in the care of a complex rheumatic disease such as SLE or RA might be seen in a study only through the carrier variable of educational attainment.

Another example is the moderately strong dose-response relationship between physical workload and the incidence of hip osteoarthritis. Farming and heavy lifting mediate this association, with an odds ratio of 3:1.⁵⁹ In this context, educational attainment is inversely related to exposure to heavy labor. Likewise, if high-salaried individuals with gratifying jobs and bonuses in their salary structures avoid disability applications for RA, whereas hourly workers do not,

this tendency might be an understandable indirect effect of education on continued employment. These complex sorts of relationships of education to clinical outcome should not obscure more direct effects, however. Education and reading level also can operate directly on visit and medication compliance and have particularly noticeable effects on outcomes of complex diseases such as RA and SLE.

PSYCHOSOCIAL INTERVENTIONS

To be a target for intervention, a psychosocial factor should be shown to be a potential cause of a clinical outcome and should be modifiable. Psychosocial factors, such as education and mood, fit these criteria and bear directly on psychosocial outcomes, such as patient satisfaction and job preservation. In addition, socioeconomic and psychosocial factors help determine biologic outcome. The effects of psychosocial factors on biologic outcome are mediated primarily by visit compliance, medication adherence and availability, and funds of knowledge about disease and the health care system. Psychosocial interventions effective in randomized clinical trials tend to revolve around the most modifiable factors (e.g., funds of knowledge). These interventions involve transfer of information or attitudes via patient education or peer support groups (see Table 67-1).

A gap between educational efforts and long-term results persists. A systematic review of 11 randomized psychoeducational interventions for patients with RA found that better designed studies showed smaller effect sizes, and long-term changes in health status (as opposed to improved knowledge per se) were not demonstrated.⁶⁰ However, at least one trial of cognitive-behavioral therapy in fibromyalgia produced physical functioning effects lasting 6 months.⁶¹

Fixed versus Modifiable Determinants

There is an obvious logic to studying psychological and social factors together. Distinct features separate psychological factors from socioeconomic factors as they apply to practice, however. First, psychological characteristics of physicians and patients are made up of fairly fixed personality traits combined with states such as mood and other modifiable factors, such as fund of knowledge about a disease or medication. In contrast to psychological states, sociologic features are almost certainly fixed. As Virchow wrote of the turbulent 1840s in Germany, "Politics is medicine written large." His observation remains applicable.⁶² In addition, because sociologic variables cannot be easily changed in a hypothesis-testing experiment, inference of causality is problematic, although analysis of variance can help.

Even when the biology of the disease is complex, the genetics heterogeneous, and access barriers likely, as in U.S. urban or rural populations with SLE, detailed analysis suggests that education and counseling, coordinated with medical care, improve outcome.⁶³ These studies found SLE disease activity and overall health status to be most strongly associated with potentially modifiable psychosocial factors, such as self-efficacy for disease management. SLE organ damage, in contrast, was best predicted by conventional clinical factors, such as duration of disease. Notably, outcomes were not associated with race. Another large study indicates that noncompliance is the largest psychosocial factor influencing outcome and confounded with race. African-American race per se had no independent effect in this large cohort in Baltimore.⁶⁴ In patients with SLE, even when the sociologic factors seem overwhelming, and the biology of the disease and its therapies complex, targeted psychosocial interventions concentrating on patient education seem to have the potential to change outcome.⁶⁵ In lupus, for example, self-efficacy and couples interactions are identified as such modifiable factors.⁶⁶

Psychosocial interventions fall into three main categories as follows: (1) efforts to improve physician-patient communication in usual care, (2) organized programs aimed at teaching or influencing groups of patients, and (3) psychopharmacology or psychotherapy. A more robust literature describes psychosocial interventions as treatment adjuncts to maximum medical treatment in ameliorating RA symptoms, improving coping and reducing disability. A recent review has reported on worksite interventions for people with RA or osteoarthritis (OA).⁶⁷ Effect sizes are modest but represent improvement that is available cheaply after even after medical therapy is maximized. The first trial, which attempted head-to-head comparison of the three basic elements of these interventions, concluded that education effect size was about equal to that attained with more expensive-to-administer stress management and cognitive-behavioral therapies emphasizing coping.⁶⁸ Thus the focus returns to patient education per se, and therefore to health literacy and physician-patient communication.⁶⁹

Physician-Patient Communication

Differing concerns, agendas, or fears; sociocultural differences; and assignment of different meanings to formulations such as "I'm fine" can all constitute barriers. *Response shift*

is the term for psychological adaptation to a worsening disease course affecting the reproducibility of responses to questions as simple as "How are you doing?" or affecting responses to more complex questionnaire instruments. Response shift could affect observer-independent measures of outcome and quality of life in studies, as well as providers' conclusions regarding individual patient encounters.⁷⁰

Canadian patients (n = 197) with established diagnoses representative of office practice except for the omission of widespread pain and fibromyalgia answered the following question⁷¹: What do patients want? Factor analysis condensed responses to questionnaires covering 32 possible concerns down to eight points. Patients asked for help in five areas and extra information in two. The five areas mentioned for help were psychological, coping, getting medication, social, and financial. The information deficits were in disease-specific areas of natural history and therapy, including conventional and unproven remedies. Physician sources and written materials were preferred. Patients with scleroderma were particularly interested in support groups. The most common worry for patients across diagnostic groups was probably the same as the number one worry of their physicians: progression of the disease. From contrasting studies, it seems that patients with SLE and their physicians have particularly divergent worries.⁷² Patients and physicians rate disease activity in SLE differently. Physicians place greater emphasis on laboratory features, whereas patients place more emphasis on function,⁷³ particularly the detrimental effects of fatigue.

Data-based recommendations for improving physician-patient communications have been derived partially from taped usual care visits and post hoc interviews with participants (Table 67-2).⁷⁴ An ethnographic approach to each individual patient, a method taken from medical anthropology, has generated a protocol for bridging sociocultural gaps between patient and provider. These seven questions, known colloquially as "the Kleinman questions," focus on determining what the patient feels is at stake in a certain disease situation (Table 67-3). These questions might also be viewed as facilitators for the first four Daltroy techniques presented in Table 67-2, which also aim to determine the patient's agenda.

Table 67-2 Techniques to Improve Communication in Usual Care Office Visits

Encourage patients to write down their concerns before each visit.
Address each concern specifically, however briefly.
Ask patients what they think has caused their problems.
Tailor treatments to patients' goals and preferences as possible.
Explain the purpose, dosage, common side effects, and inconveniences, and how to judge the efficacy of each treatment, including length of trial.
Assess patients' understanding.
Anticipate problems in compliance with treatment plans, and discuss methods to cope with common problems.
Write down diagnosis and treatment plan to help patients remember.
Distribute written materials that are now widely available.
Reinforce patients' confidence in their ability to manage their regimen.
Use ancillary personnel in patient education.
Refer patients to organized programs in the community.

Time Constraints

Time constraints in the context of usual care office visits argue for maximal use of organized programs and for the use of self-completed questionnaires and forms, such as the American College of Rheumatology new patient form. Patients sometimes see forms as an imposition if they are not referred to in the subsequent interview. If the form is part of the conversation and is even marked with a few highlights or marginal notes, it is interpreted as an element of thoroughness. Scheduled telephone contact is poorly reimbursed but is effective enough to reduce knee pain from osteoarthritis in a randomized study.⁷⁵ Legal and institutional restrictions notwithstanding, a reasonable rule of thumb for clinical e-mail is to use it for nothing more sensitive than what would be said over the telephone.⁵⁸ Overall, the main psychosocial impact of time pressure is to make the interview more physician-directed than patient-directed, putting up an obstacle to physician-patient communication.⁷⁶

Organized Programs

A variety of interventional programs improve outcome measured in their own terms when other psychosocial variables or a health status scale are the primary outcomes. These include support groups, which improve coping more than half the time,⁷⁷ and stress management,⁷⁸ group psychotherapy,⁵⁸ and prayer.⁷⁹ A smaller number (see Table 67-1) also save money, improve pain, protect anatomy, and have a durable effect. Exercise programs are effective, but patients have difficulty sustaining the effort these programs require over time.

Psychotherapy and Psychopharmacologic Interventions

Depression often goes unrecognized. With a psychiatric telephone interview in a survey study taken as the “gold standard,” only about 19% of depressed individuals were diagnosed and treated in the course of usual care over 1 year.⁸⁰ Treatment was less likely for men, African-Americans, and individuals with lower educational levels. Individuals 30 to 60 years old were more likely to get treatment. Brief psychotherapy and antidepressants are effective. Depression in rheumatic disease occurs more frequently in particular settings, including patients reporting widespread chronic pain, patients coming to grips with work disability, and patients presenting at a young age with knee osteoarthritis.

More recent findings in relevant psychopharmacology include selective serotonin reuptake inhibitor equivalence for efficacy across the class.⁸¹ Recognition of large relative increases in the risk of sudden cardiac death on moderate doses of antipsychotics has also increased.⁸²

SUMMARY

The results of patient education and psychosocial intervention seem modest compared with very effective, biologically based interventions such as tumor necrosis factor blockade. The latter costs about \$18,000 to \$25,000 per year and makes inroads into the lifetime loss of 16 quality-adjusted life-years per the average 27-year course of RA, including 6.6 years of lost survival that were incurred in the absence of biologics and methotrexate. In contrast, the best organized and delivered psychosocial intervention administered on a group basis, the Arthritis Foundation Self-Help Course, has minimal costs and cuts outpatient visits by 40%, saving each osteoarthritis patient and RA patient less than \$300 per year.

Meta-analyses and reviews indicate that organized programs aimed at specific subsets of rheumatic disease patients have effects that are favorable, but the effect sizes are small, making them hard to measure, and the effects on outcomes not purely within psychosocial domains are hard to find. Finally, it is difficult to prove effects that are sustained over time.^{83,84} Specific psychosocial management techniques stand as modest adjuncts to powerful specific therapy but must be understood as the middle part of a range of promising opportunities.

Increasing health literacy and improving individual physician-patient communications are effective psychosocial interventions, along with recognition and treatment of concomitant depression. Large-scale social interventions, such as improving the reading level of the patient population where health literacy is lacking, would change disease outcome more than psychosocial interventions aimed at individual diseases. Interpreted broadly over their whole range, including health literacy, psychosocial management techniques are potentially as powerful as biologic therapies. Organized programs applied to defined patient subgroups are the most easily measured and discussed interventions in a scientific sense, however. This thought illustrates French anthropologist-philosopher Rene Dubois' dictum that “the measurable drives out the important,” which still leaves individual patients and their physicians a fascinating set of possibilities to study and apply, and from which to benefit.

KEY POINTS

Nutritional factors can have proinflammatory or anti-inflammatory effects, or both.

Nutritional factors have been implicated in the etiology of a variety of rheumatic disorders including gout and rheumatoid arthritis (RA).

Many patients with rheumatic disease believe diet plays an important role in their symptoms.

Dietary supplementation with fish oil can reduce signs and symptoms of inflammation, as well as reduce the need for nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with RA.

RA, systemic lupus erythematosus, gout, and NSAID use have been linked to increased risk for thrombotic cardiovascular events. Fish oil supplements can reduce frequency of sudden cardiac death and improve blood lipid profiles.

Nutrition and Rheumatic Diseases

NUTRITION AND THE INFLAMMATORY PROCESS

KEY POINTS

Omega-3 fatty acids are immunoregulatory.

Vitamin D has multiple immunosuppressive effects.

Antioxidants can be acquired through the diet.

Adipose tissue is metabolically active and has effects on the inflammatory response.

Probiotics have anti-inflammatory properties.

Role of Omega-3 Fatty Acids and the Inflammatory Process

Fatty Acid Biochemistry

Fatty acids are divided into three groups on the basis of the number of double bonds they contain (saturated fatty acids (no double bond), monounsaturated fatty acids (one double bond), and polyunsaturated fatty acids (PUFAs) (≥ 2 double bonds)). C18 fatty acids are prominent in the diet and provide the index fatty acids for the above classification. PUFAs are further grouped according to the site of the double bond proximal to the methyl (omega) terminus as n-6 or n-3. Vertebrates do not have the enzymes required to introduce double bonds in the n-3 and n-6 positions; therefore these fatty acids must be obtained from the diet and are thus known as essential fatty acids.

In general, the Western diet contains more n-6 fats than n-3 fats due to the dominance in processed foods and visible fats of soybean, safflower, sunflower, and corn oils, which contain the n-6 fat linoleic acid (LA; 18:2n-6). The n-3 homologue of LA, α -linolenic acid (ALA; 18:3n-3), is present in flaxseed oil, which is generally a minor dietary component. LA and ALA may be used in energy metabolism or be converted to the C20 fatty acids arachidonic acid (AA) and eicosapentaenoic acid (EPA), respectively. AA and EPA are then incorporated into cell membranes and tissues. EPA can be further metabolized to the n-3 fatty acid docosahexaenoic (DHA).

The critical process linking fatty acids and inflammation is the metabolism of AA and EPA to eicosanoids, which act as inflammatory mediators. AA is metabolized via cyclooxygenase (COX) to n-6 eicosanoids (prostaglandin [PG] E₂, thromboxane [TX] A₂ or via 5-lipoxygenase [5-LOX] to n-6 leukotrienes [LTs]). In comparison, EPA is metabolized via COX and 5-LOX to n-3 PGs and LTs, respectively. In comparison to the n-6 eicosanoids produced from AA, EPA is

Nutrition plays a role in the management of most chronic diseases. Physicians provide dietary advice to patients with diabetes, heart disease, and obesity as part of standard clinical care. Although the role of diet and nutrition is well established in the etiology and management of gout, the role of nutrition in other rheumatic diseases such as rheumatoid arthritis (RA) is less well accepted. In general, dietary advice is not part of standard clinical practice for patients with inflammatory rheumatic diseases. Despite a widespread lack of conviction among physicians about the role of nutrition, many people with arthritis believe food plays an important role in their symptom severity and approximately 50% will have tried dietary manipulation in an attempt to improve their symptoms.¹

It is well recognized that inflammatory disease processes can interfere with nutritional status. More recently, the impact of nutritional factors on the inflammatory response has been recognized. Furthermore, diets and lifestyles have changed considerably through industrialization with significant effects on rates of obesity, food choices, and consumption of different dietary components. In light of this, the role nutrition in the etiology and management of rheumatic diseases is becoming increasingly important.

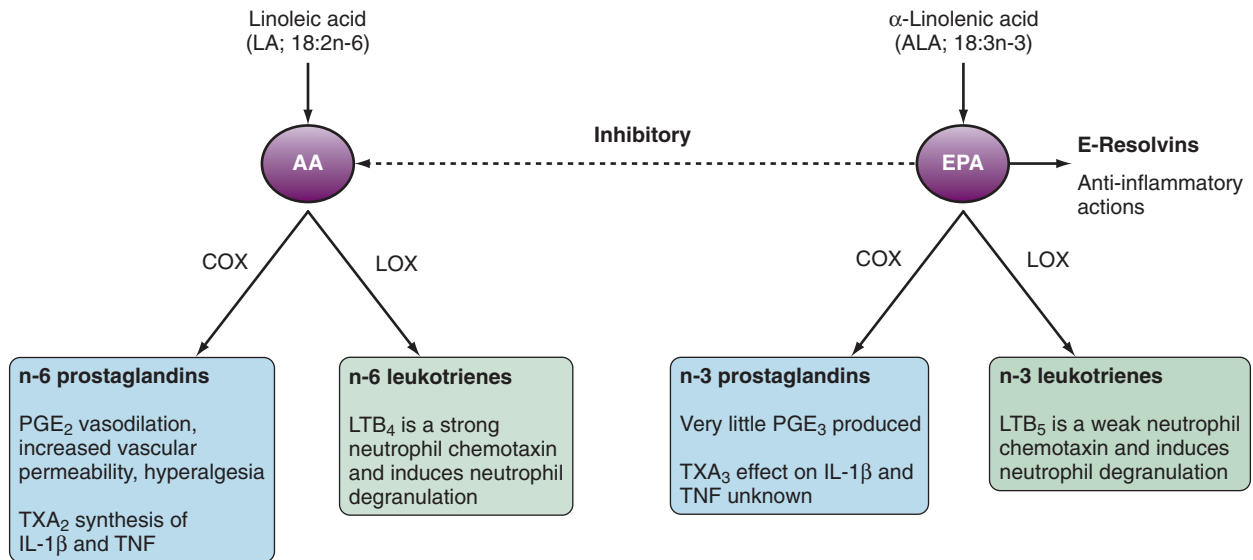

Figure 68-1 Metabolism of linoleic acid (LA) and α-linolenic acid (ALA) to n-6 and n-3 prostaglandins and leukotrienes. AA, arachidonic acid; COX, cyclooxygenase; EPA, eicosapentaenoic acid; IL-1β, interleukin-1β; LOX, lipoxygenase; LTB, leukotriene B; PGE, prostaglandin E; TNF, tumor necrosis factor; TXA, thromboxane A.

a poor COX substrate such that n-3 PGs are not as readily produced (Figure 68-1). EPA and DHA competitively inhibit production of most n-6 eicosanoids, with prostacyclin (PGI₂) being an exception. Increased dietary consumption of n-3 fatty acids such as EPA increases the proportion of EPA incorporated in cellular membranes and tissues partly at the expense of AA incorporation. The net result is an alteration in the balance of n-3/n-6 eicosanoid production (see Figure 68-1).

Proinflammatory Actions of Eicosanoids

In general the n-6 eicosanoids (PGE₂ and TXA₂) are proinflammatory, whereas the n-3 eicosanoids are either less potent in their effects (TXA₃) or less abundant (PGE₂). TXA₂ promotes interleukin-1β (IL-1β) and tumor necrosis factor (TNF) production by mononuclear cells,² whereas PGE₂ results in vasodilatation, increased vascular permeability, and hyperalgesia (see Figure 68-1). PGE₃ is edemogenic, although little is produced. LTB₅ is 10 to 30 times less potent than LTB₄ as a neutrophil chemotaxin.

Effect of n-3 Fatty Acids on Proinflammatory Cytokine Production

IL-1β and TNF production may be reduced as a consequence of dietary n-3 fatty acid supplementation. Although some of this cytokine inhibition is mediated through effects on eicosanoids, there also appears to be eicosanoid-independent cytokine inhibition. For example, fatty acids may have direct effects on intracellular signaling mechanisms including nuclear factor κB (NFκB) and PPAR-γ, thereby affecting cytokine production.³

The resolvins (resolution phase interaction products) are derived from n-3 fatty acids via COX-2 with increased production in the presence of aspirin. Resolvins derived from EPA are known as E-resolvins, whereas those derived from DHA are known as D-resolvins. The resolvins have a variety

of anti-inflammatory actions including inhibition of TNF-induced transcription of IL-1β and inhibition of human polymorphonuclear leukocyte transendothelial migration (for review, see Kohil and Levy's study⁴). The identification of resolvins provides another mechanism through which n-3 fatty acids contribute to inhibition of inflammatory cytokine production.

Effects of n-3 Fatty Acids on MHC Expression

The number of MHC molecules expressed on antigen-presenting cells (APCs) is an important determinant of T cell response to antigen. Patients with RA have high levels of MHC class II expression on T cells and synovial lining cells.⁵ In vitro studies show that EPA and/or DHA reduces monocyte expression of HLA-DR and HLA-DP molecules and reduces the ability of monocytes to present antigen to autologous lymphocytes.⁶ Thus n-3 fatty acids may have an anti-inflammatory effect via suppression of pathogenic T cell activation through inhibition of APC function.

Effect of n-3 Fatty Acids on Adhesion Molecule Expression

Adhesion molecules expressed on endothelial cells and leukocytes mediate the transit of cells from the circulation into tissues. Intercellular adhesion molecule-1 (ICAM-1) and its cognate receptor, leukocyte function-associated antigen (LFA)-1, have been shown to be important in migration of leukocytes into inflamed synovium in animal models.⁷ ICAM-1 blockade has also been reported to reduce disease activity in RA.⁸ In vitro n-3 fatty acids decrease human monocyte ICAM-1 and LFA-1 expression.⁶ In addition, dietary n-3 fatty acid supplementation reduces soluble ICAM-1 and vascular cell adhesion molecule-1 (VCAM-1) plasma concentrations,⁹ although whether cell surface expression of these adhesion molecules is also reduced has not been reported.

Effect of n-3 Fatty Acids on Degradative Enzymes

Proteinases have a pivotal role in cartilage degradation and bone erosion. n-3 Fatty acids added in vitro can suppress proteinases ADAMTS-4, ADAMTS-5, and MMP-3 in IL-1 α stimulated bovine chondrocytes.¹⁰ This inhibition of chondrocyte proteases is a mechanism through which n-3 fatty acids may inhibit cartilage degradation and bone erosion.

The RANK/RANKL/OPG pathway is also important in bone pathophysiology in RA. Increased RANK/RANKL and decreased OPG contribute to bone erosion. Three months of dietary fish oil supplementation has been reported to decrease the RANK/OPG ratio, which may help prevent bone resorption that leads to erosions.¹¹

Importance of the Balance of n-3 and n-6 Fatty Acids in the Inflammatory Process

The balance of AA and EPA can be altered through dietary fatty acid intake. In humans, the conversion of dietary ALA to tissue EPA is inefficient and fish/fish oils are a more effective way to increase EPA and DHA in tissues. Changes in AA/EPA ratios in tissues have downstream effects on eicosanoid production and the resulting proinflammatory/anti-inflammatory environment. Dietary supplementation with fish oil in humans results in decreased production of PGE₂,¹² TXA₂,¹² and LTB₄¹³ with increased production of TXA₃¹⁴ and LTB₅.¹⁵ These data provide a mechanistic basis for beneficial effects of dietary n-3 fatty acid supplementation in the control of inflammatory diseases. Dietary fish oil supplements have been shown to increase vascular production of prostacyclin (PGI₂).¹⁶ Although the role of PGI₂ in inflammation is not well defined, it is a potent vasodilator and inhibits platelet aggregation, as well as disaggregating platelets. These effects likely contribute to the protective effects of dietary fish and fish oils against thrombotic vascular events. Importantly, patients with several of the major rheumatic diseases (e.g., RA, systemic lupus erythematosus [SLE] and gout) are at high risks for serious cardiovascular events and mortality, to which nonsteroidal anti-inflammatory drug (NSAID)-associated COX-2 inhibition may also contribute.

Vitamin D and the Inflammatory Process

Vitamin D has multiple immunosuppressive effects in addition to its effects on bone and calcium metabolism. The biologically active form of vitamin D (1,25-dihydroxyvitamin [OH]₂ D₃) interacts with vitamin D receptors, which are expressed on a variety of cells including osteoblasts, T cells, dendritic cells (DCs), macrophages, and B cells. These cells also have the capacity to convert more abundant 25(OH) D₃ to 1,25(OH)₂ D₃ and to degrade 1,25(OH)₂ D₃. Accordingly, the molecular machinery is in place for important autocrine and paracrine effects of vitamin D at sites of inflammation.

DCs have a central role in activation of the immune system and in response to self. 1,25(OH)₂ D₃ inhibits the differentiation of monocyte precursors into mature DCs, downregulates expression of MHC class II molecules on DCs, inhibits IL-12 production, and promotes DC

apoptosis, thereby inhibiting DC-dependent T cell activation.^{17,18} In addition, 1,25(OH)₂ D₃ can promote DC expression of tolerizing functions, which instruct T regulatory (Treg) cells, which in turn may inhibit the development of autoimmunity.¹⁹ Vitamin D inhibits monocyte/macrophage proinflammatory cytokine production including TNF, IL-6, and IL-1 α .²⁰ Vitamin D has direct effects on T cells, in particular inhibition of proliferation and cytokine production by Th1 cells, and may enhance Th2 cytokine production.²¹ 1,25(OH)₂ D₃ has also been shown to reduce Th17 cell differentiation through its effects on DCs, as well as direct effects on Th17 cells leading to reduced IL-17A production.^{19,22} 1,25(OH)₂ D₃ inhibits the proliferation of activated B cells, induces activated B cell apoptosis, and inhibits plasma cell differentiation and immunoglobulin secretion.²³ Thus vitamin D deficiency may have a role in the etiology of B cell-mediated autoimmune disorders, whereas vitamin D supplementation may have beneficial effects in B cell-mediated autoimmune diseases such as SLE and RA.

The array of relevant effects of vitamin D on the immune system suggests that vitamin D insufficiency may have an important role in the etiology and management of rheumatic diseases more generally.

Reactive Oxygen Species/Antioxidants and the Inflammatory Process

Production of reactive oxygen species (ROS) such as superoxide and hydrogen peroxide are part of the normal immune response. ROS acting through transcription factors such as NF κ B increase production of proinflammatory eicosanoids and cytokines including PGE₂, TNF, and IL-1 β . Thus unchecked production of ROS may cause inflammation and tissue damage. Antioxidant enzymes such as superoxide dismutase and glutathione peroxidase remove superoxide, thus providing protection from oxidative damage. Vitamin C (ascorbic acid), vitamin E (α -tocopherol), and β -carotene are acquired through the diet and can act as ROS scavengers.

Obesity and the Inflammatory Process

With excess energy intake and reduced energy expenditure, body weight and adiposity increase. Obesity (body mass index [BMI] > 30 kg/m²) is a significant health problem globally with the World Health Organization estimating that by 2015 approximately 2.3 billion adults will be overweight and more than 700 million will be obese.

Adipose tissue was originally thought to be simply a fat store. However, it is now recognized that adipose tissue and adipocytes are metabolically active and contribute to systemic inflammatory responses (Figure 68-2). Adipocytes release the proinflammatory cytokines TNF, IL-1 β , and IL-6. IL-6 enters the systemic circulation and increases C-reactive protein and serum amyloid A production by the liver.

Adipocytes produce adipokines; leptin, resistin, and visfatin (proinflammatory); and adiponectin (anti-inflammatory) (see Figure 68-2). Although the primary function of leptin is appetite control, it also has a number of proinflammatory actions. Leptin increases the expression of adhesion molecules such as ICAM-1 and monocyte

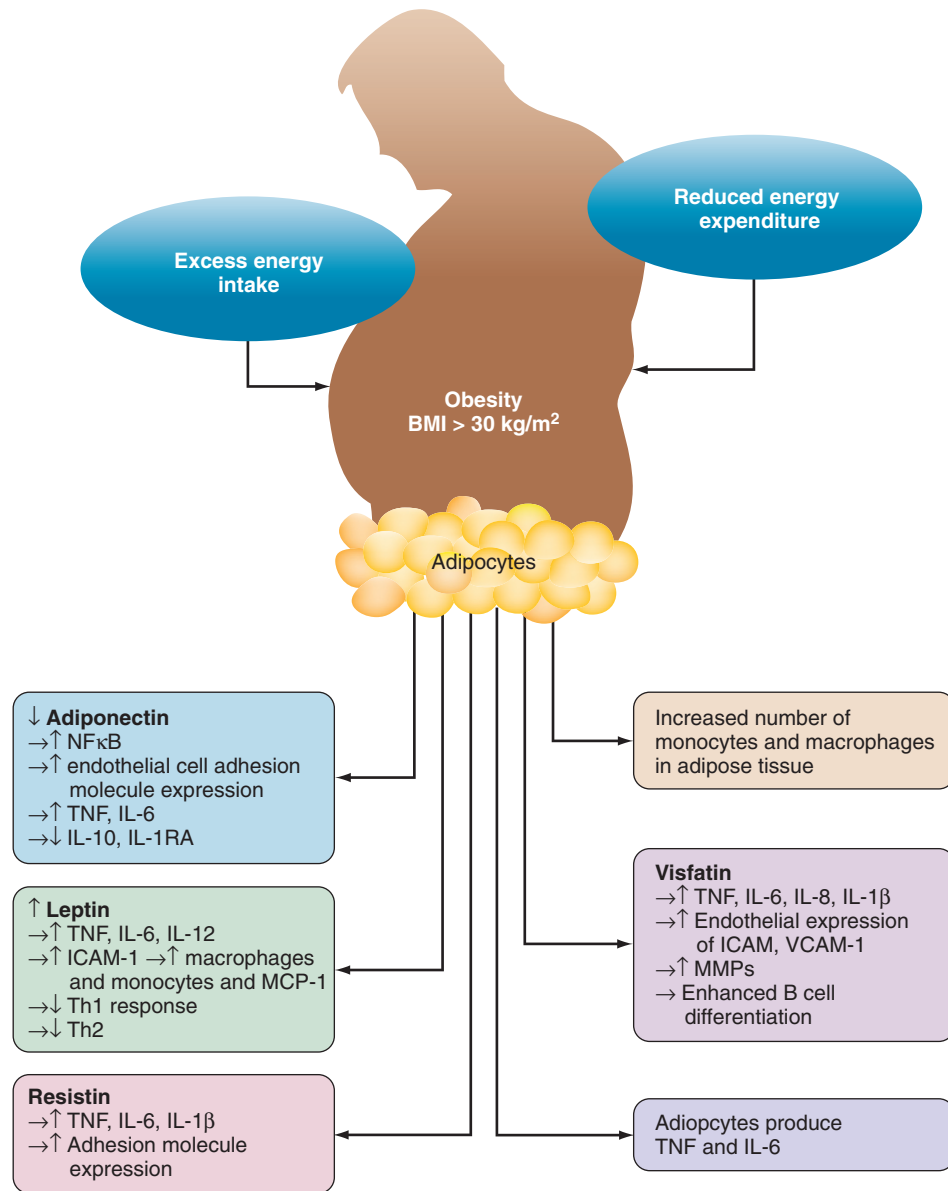

Figure 68-2 Inflammatory mechanisms of obesity. BMI, body mass index; ICAM, intercellular adhesion molecule; IL, interleukin; MCP-1, monocyte chemoattractant protein; MMPs, matrix metalloproteinases; NFκB, nuclear factor κB; Th, T helper; TNF, tumor necrosis factor; VCAM-1, vascular cell adhesion molecule-1.

chemoattractant protein-1 (MCP-1) thereby favoring recruitment of monocytes/macrophages into adipose tissue. Leptin also increases IL-1β, TNF, and IL-6 production by monocyte/macrophage. Leptin activates T cells, increasing proliferation of Th1 cells while inhibiting Th2 cells. The anti-inflammatory effects of adiponectin include inhibition of TNF-induced adhesion molecule expression; inhibition of NFκB, a pivotal intracellular factor in activation of inflammatory responses; and production of the anti-inflammatory cytokines IL-10 and IL-1RA. Production of adiponectin is inhibited by TNF, which thereby helps sustain the proinflammatory alteration of homeostasis found in obesity. Resistin is produced by mononuclear cells and adipocytes. Resistin increases macrophage/monocyte and adipocyte production of TNF, IL-6, and IL-1β and also increases expression of the adhesion molecules ICAM-1, VCAM-1, and MCP-1.²⁴ Visfatin, which is produced by

lymphocytes and adipocytes, has similar proinflammatory effects including induction of IL-8, IL-6, IL-1β, and TNF; increased endothelial expression of ICAM-1, VCAM-1, and MMPs; and enhancement of B cell differentiation.²⁴ The net result of obesity is thus an inflammatory state associated with an increase in circulating C-reactive protein.

Probiotics and the Inflammatory Process

Probiotics are defined as live microorganisms, which confer a health benefit to the host. The most common probiotics are lactobacilli and bifidobacteria. These organisms are present in foods, commonly dairy fermented products such as yogurt, as well as in supplements such as probiotic drinks in lyophilized form. Probiotics have anti-inflammatory properties, with the mechanism of anti-inflammatory action varying between different probiotics species and different

species strains. Thus although certain probiotic strains may confer health benefits, these benefits may not be seen with other probiotic species or strains.

Probiotics may exert their putative anti-inflammatory effects by interacting with intestinal epithelial cells. Resultant modulation of intestinal microflora and fortification of intestinal barrier function may lead to altered exposure of the immune system to microbes and direct effects on immune cells within the intestine. Associated effects relevant to anti-inflammatory responses include accumulation of CD4⁺ Treg cells in inflamed areas²⁵; inhibition of DC activation²⁶; antagonism of NFκB, which leads to decreased IL-1β and TNF production; and induction of the inflammation-modulating cytokine TGF-β.

Summary

Dietary components can have a variety of effects on the inflammatory process and on bone destructive pathways (Table 68-1). Thus alterations in diet may have effects on both the risk and management of rheumatic diseases, as discussed later.

Table 68-1 Effects of Dietary Components on Inflammatory and Bone Destructive Pathways

n-3 Fatty Acids
Decreased production of n-6 derived eicosanoids (PGE ₂ , TXA ₂ , LTB ₄), which have proinflammatory effects
Increased production of n-3-derived eicosanoids (PGE ₃ , TXA ₃ , LTB ₅), which in general are less proinflammatory
Decreased IL-1β and TNF production
Increased production of resolvins
Decreased major histocompatibility complex II expression by antigen-presenting cells
Decreased adhesion molecule expression: ICAM, VCAM, LFA
Decreased expression of matrix metalloproteinases
Alteration in RANK/OPG ratio
Vitamin D
Inhibition of monocyte differentiation into DCs and promotion of DC apoptosis
Induction of tolerogenic Tregs with enhanced suppressive activity
Inhibition of monocyte/macrophage IL-1β and TNF production
Inhibition of Th1 cell proliferation and cytokine production
Enhancement of Th2 cytokine production
Reduction in Th ₁₇ cell differentiation and IL-17A production
Inhibition of proliferation of activated B cells, differentiation of activated B cells and immunoglobulin secretion
Antioxidants
Scavenge reactive oxygen species
Reduce proinflammatory eicosanoids, TNF and IL-1β
Probiotics
Generation of CD4 ⁺ Tregs in inflamed areas
Inhibition of DC activation
Decreased IL-1β and TNF production via inhibition of nuclear factor κB
Increased production of transforming growth factor-β

DC, dendritic cell; ICAM, intercellular adhesion molecule; IL, interleukin; LFA, leukocyte function-associated antigen; LTB, leukotriene B; PGE, prostaglandin E; RANK/OPG, receptor activator of nuclear factor κB/osteoprotegerin; Th, T helper; TNF, tumor necrosis factor; TXA, thromboxane A; VCAM, vascular cell adhesion molecule.

NUTRITION IN THE ETIOLOGY OF RHEUMATIC DISEASES

Rheumatoid Arthritis

KEY POINTS

Assessing dietary intake is difficult, and identifying a single dietary factor may not be possible.

Omega-3 fatty acids may protect against RA.

The association between vitamin D and RA remains unclear.

Obesity may affect disease activity and outcomes in RA.

A number of epidemiologic studies have examined the role of nutrition in the etiology of RA. Assessing dietary intake in epidemiologic studies is difficult, and identifying the effects of a single dietary variable and distinguishing it from other nutritional and lifestyle factors may not be possible. Notwithstanding, a number of nutritional factors are candidates for an association with the development of RA.

Omega-3 Fatty Acid Consumption

The long chain n-3 fats, EPA and DHA, are most abundant in fish and fish oils. A protective effect against RA of fish intake has been reported. For example, the Seattle Women's Health Study showed reduced risk for developing RA in subjects consuming two or more fish meals per week with an adjusted odds ratio (OR) of 0.57 (95% confidence interval [CI], 0.35 to 0.93) compared with subjects consuming less than one fish meal per week.²⁷ A more recent population-based, case-controlled study reported a modest decrease in the risk of RA in subjects who consume oily fish one to seven times per week compared with those who seldom or never consumed fish (OR, 0.8; 95% CI, 0.6 to 1.0), which did not change even allowing for RF and anticyclic citrullinated protein (CCP) antibody status.²⁸

Red Meat and Protein Consumption

High consumption of red meat has been associated with an increased risk of inflammatory polyarthritis (OR, 1.9; 95% CI, 0.9 to 4.0).²⁹ Although one study reported that meat and offal were associated with an increased risk of developing RA,³⁰ this was not confirmed in other studies.^{31,32} Whether the association between red meat consumption and inflammatory arthritis is causative remains unclear, although the presence of significant amounts of AA in red meat may provide some explanation for the association.

Tea and Coffee Consumption

Tea and coffee have been identified as potential risk factors for the development of RA. In the Finnish National Health Study, consumption of four or more cups of coffee per day was associated with an increased risk of RF-positive, but not RF-negative, RA after adjustment for potential confounders such as age, smoking, and gender (relative risk [RR], 2.2; 95% CI 1.13 to 4.27).³³ By contrast, the Iowa Women's

Health Study reported no association between daily caffeine intake and risk for RA. However, women who consumed four or more cups of decaffeinated coffee per day were at increased risk for RA compared to non-coffee drinkers (RR, 2.58; 95% CI, 1.63 to 4.06). Furthermore, women who consumed three or more cups of tea per day had a reduced risk of RA (RR, 0.39; 95% CI, 0.16 to 0.97).³⁴ More recent studies have not shown an association between tea/coffee and RA.^{31,35}

Although the epidemiologic evidence for an association between coffee/tea and RA is equivocal, interest has been sustained by the presence of metabolically active agents in these beverages. For example, the major catechin in tea inhibits induction of inducible nitric oxide synthase (iNOS) by stimulated macrophages.³⁶ iNOS generates highly reactive free radical products while di-imidating substrate arginine moieties to citrulline. Citrullinated peptides/proteins are recognized immunogens that provide a focus for autoimmunity in RA.

Alcohol Consumption

Alcohol consumption may reduce the risk of developing RA. In a case-control study of 515 patients with RA, alcohol consumption was associated with a reduced risk of anti-CCP positive RA.³⁷ A dose-dependent inverse relationship between alcohol consumption and risk of RA has also been demonstrated from two independent case-control studies (Swedish EIRA and Danish CACORA).³⁸ The reduction in risk of RA was more pronounced in patients with the shared epitope compared those without the shared epitope and most pronounced in smokers with the shared epitope.³⁸

With regard to candidate mechanisms for this putative reduction in risk for RA, alcohol has been shown to down-regulate the production of proinflammatory cytokines and upregulate production of the anti-inflammatory cytokine IL-10.^{39,40} Furthermore, in a murine model of arthritis, ethanol almost totally prevented the development of collagen-induced arthritis and in those mice that did develop arthritis, disease was less severe. These anti-inflammatory effects of ethanol were associated with reduced leukocyte migration, downregulation of NF κ B, and reduced production of the proinflammatory cytokines IL-6 and TNF but not the anti-inflammatory cytokine IL-10.⁴¹

Vitamin D

As noted earlier, vitamin D has anti-inflammatory actions. Although vitamin D has been implicated in reducing the risk of the autoimmune diseases, diabetes,⁴² and multiple sclerosis, the association with risk of RA is less clear.⁴³

The Iowa Women's Health Study reported that a higher intake of vitamin D was associated with a reduced risk of RA (RR, 0.67; 95% CI, 0.44 to 1.00, $P = 0.05$) in women aged 55 to 69 years.⁴⁴ However, in a more recent large study of 186,389 women followed for 22 years, there was no association between dietary intake of vitamin D and the risk of developing RA.⁴⁵ However, apart from supplements, the main source of vitamin D is *de novo* synthesis in the skin and estimated dietary intake may be a poor predictor of serum vitamin D concentrations. In a study of 79 patients with RA, no association was found between prior serum

vitamin D concentrations and subsequent development of RA.⁴⁶ However, it is notable that the geometric means for both cases and controls in this study were only half the lower reference level of 60 nmol/L, which has been set subsequently to reflect a level that suppresses secondary hyperparathyroidism due to vitamin D insufficiency.

Antioxidants and Risk of Rheumatoid Arthritis

Oxygen free radicals (e.g., nitric oxide, superoxide, hydroxyl radical) are implicated in the tissue damage observed in RA.⁴⁷ Antioxidants including vitamin E (α -tocopherol), vitamin C (ascorbic acid), β -carotene, and selenium may have a protective role against tissue damage caused by these oxygen free radicals. This combined with evidence that markers of antioxidant nutritional status are lower in patients with established RA compared with normal controls⁴⁸ led to the hypothesis that antioxidants may protect against the development of RA. Despite this biologic plausibility, the available data do not provide clear evidence for a protective effect of antioxidants as dietary supplements in relation to the development of RA.

Low serum concentrations of vitamin E, β -carotene, retinol, and selenium have been reported to be weakly associated with an increased risk for developing RA in some but not all studies.⁴⁹⁻⁵¹ The strongest association between risk of RA and antioxidants was found for a combined antioxidant index rather than any one specific antioxidant.⁴⁹

A higher dietary intake of β -cryptoxanthin (a carotenoid found in fruit and vegetables) and zinc may protect against the development of RA.^{52,53} Low vitamin C intake has also been associated with an increased risk of inflammatory polyarthritis with an adjusted OR of 3.3 (95% CI, 1.4 to 7.9) for the lowest tertile of vitamin C intake (<55.7 mg/day) compared with the highest intake tertile (>94.9 mg/day).⁵⁴ However, another study found no association between intake of vitamin C, vitamin E, zinc, or selenium and the development of RA.³¹

The Women's Health Study, a randomized, double-blind, placebo-controlled trial designed to evaluate the effects of low-dose aspirin and vitamin E in the primary prevention of cardiovascular disease and cancer, has been used to address the influence of vitamin E supplementation (600 IU on alternate days) on the development of RA. During the 10-year follow-up period, 106 cases of RA occurred with no significant association between vitamin E supplementation and incidence of RA. A statistically insignificant trend toward inverse association between vitamin E and development of seropositive RA was seen on subgroup analysis.⁵⁵

Obesity and Rheumatoid Arthritis

Two studies have reported that obesity increases the risk of RA,^{56,57} whereas two other studies report no association.⁵⁸⁻⁶⁰ Increased plasma concentrations of the adipokines leptin, adiponectin, and visfatin have been observed in patients with RA compared with healthy controls.⁶¹ Furthermore, visfatin and leptin were associated with increased and reduced radiographic joint damage, respectively.⁶¹ These data combined with the proinflammatory state observed in obesity suggest that BMI may affect disease activity and outcomes in RA, whereas, perhaps paradoxically, increased

BMI has been associated with less radiographic damage.^{58,62} An alternative explanation is that patients with more active inflammatory disease, who tend to develop more radiographic erosions, may have lower BMI and rheumatoid cachexia.

Gout

KEY POINTS

The link between diet and gout has been recognized for centuries.

High intake of meat, seafood, and alcohol is associated with increased risk of gout.

Fructose increases serum urate.

Higher intake of low-fat dairy products has been associated with a reduced risk of gout.

Increased BMI predisposes to gout.

For centuries gout has been associated with overindulgence in rich food and wine. Gout occurs when serum urate (SU) concentrations reach super-saturation concentrations (≈ 6.8 mg/dL at 37° C), resulting in the formation of monosodium urate crystals, which deposit in joints and soft tissues. Urate is the end product in the breakdown of purines, which are a product of cellular turnover or are ingested in the diet. The purines adenosine and guanine are present in nucleic acids and the intracellular energy transporters adenosine triphosphate and guanosine triphosphate. Accordingly, foods derived from metabolically active animal tissues may increase dietary purine load.

Dietary Factors and Gout

Several large clinical studies have identified an association between high intake of meat and seafood (but not total protein intake) and both SU concentrations⁶³ and gout.⁶⁴ In comparison, the risk of gout is reduced with higher intake of low-fat dairy products and long-term coffee consumption.^{64,65} More recently, fructose, which is found in corn syrup, sugar-sweetened soft drinks, and fruit juices, has been associated with hyperuricemia and gout.^{66,67} Fructose increases SU through increased purine degradation.⁶⁸ Furthermore, urate and fructose share a common transporter within the kidney (SLC2A9).⁶⁹ Alcohol consumption other than moderate wine intake is associated with an increased risk of gout, with beer conferring a higher risk than liquor.⁷⁰

Dietary vitamin C supplementation has been shown to reduce the risk of gout (relative risk of gout with no supplementation vs. 1000 to 1499 mg vitamin C/day, 0.66 [95% CI, 0.49 to 0.88]).⁷¹ Vitamin C (ascorbic acid) is an important vitamin that can only be obtained through dietary intake. Because ascorbic acid is water soluble, it is not stored within the body and thus must be regularly supplemented through the diet to maintain the ascorbic acid pool. Dietary sources of ascorbic acid include fresh fruits and vegetables, in particular citrus fruits and green leafy vegetables such as broccoli.

Fasting and Gout

Prolonged periods (2 weeks to 8 months) of fasting in obese subjects result in a significant increase in SU and in some cases the development of gout.⁷² In patients with previously documented gout, a 1-day fast led to an increase in SU of 0.5 to 2.1 mg/dL with a mean rise of 1.1 mg/dL, with refeeding associated with a return in SU to baseline levels after 24 hours.⁷³ Explanations for the increase in SU during fasting include increased urate production, decreased excretion due to decreased glomerular filtration rate, altered renal tubular transport of uric acid, and competition with ketones for renal tubular excretion.⁷⁴

Obesity and Gout

High BMI predisposes to gout.⁷⁵ In a study comparing obese men (mean BMI 34 ± 4 kg/m²) with healthy controls (BMI, 21 ± 1 kg/m²), SU concentrations were raised to a similar degree in the obese subjects ($\approx 8.0 \pm 1.6$ mg/dL vs. controls, 5.2 ± 0.81 mg/dL), irrespective of body fat distribution (predominantly visceral or predominantly subcutaneous). By contrast, 80% of subjects with hyperuricemia and accumulation of fat subcutaneously had low 24-hour urinary urate excretion compared with 10% of their counterparts with fat accumulation predominantly in a visceral distribution. These data suggest that the mechanism of hyperuricemia may vary depending on body fat distribution.⁷⁶ In a separate study using computed tomography to determine transverse area of abdominal fat components, visceral fat was shown to correlate strongly with SU, whereas no relationship was seen between SU and BMI or subcutaneous fat area.⁷⁷

Osteoarthritis

KEY POINTS

Obesity is associated with knee osteoarthritis (OA).

Direct biomechanical effects of obesity contribute to OA.

Increased leptin provides another link between obesity and OA.

Associations have been established between obesity and onset and progression of knee OA. The evidence for an association between obesity and OA of the hip or hand is less well defined. In addition to direct biomechanical effects of obesity on the joint, recent data suggest a role for the adipocytokine leptin. Expression of leptin was increased in advanced OA cartilage compared with minimally damaged OA cartilage, with the leptin mRNA expression in advanced OA cartilage correlating with BMI. Furthermore, leptin was shown to reduce chondrocyte proliferation and increase IL-1 β , MMP-9, and MMP-13 expression.⁷⁸

Dietary antioxidants (vitamin E, vitamin C, and β -carotene) have been reported to reduce progression of knee OA but have no effect on onset of OA.^{79,80} The association between serum vitamin D concentrations and OA remains unclear, with one study reporting no association between vitamin D and risk of joint space narrowing or cartilage loss in knee OA⁸¹ and another study reporting a

positive association between knee cartilage volume and serum vitamin D concentrations.⁸²

NUTRITION IN THE MANAGEMENT OF RHEUMATIC DISEASES

The role of nutrition in the management of gout is well accepted. However, its role in other rheumatic diseases such as RA is less routine. Despite a relative lack of interest or emphasis from physicians, many patients consider food may contribute to their arthritis and seek information about or try putative dietary remedies. A convincing, informed approach to nutritional advice is thus an important aspect of management, which can help patients avoid worthless interventions that are expensive, time consuming, in some cases harmful, and diversions from access to more effective measures (summarized in Figure 68-3). Furthermore, positive advice regarding dietary choices may empower the

patient at a time when there is often a sense of loss of control. Well-informed, authoritative dietary advice can also protect patients from poorly grounded advice from relatives, friends, and nonauthoritative Internet sites about dietary measures.

Rheumatoid Arthritis

KEY POINTS

Omega-3 fatty acids reduce disease activity and NSAID requirement.

There is no evidence for benefit of antioxidants in the management of RA.

Fasting, vegetarian/vegan, and elimination diets are difficult to sustain, and it is difficult to predict which patients may respond.

	Gout	RA
 Alcohol	↑ SU ↑ Risk of gout	May ↓ risk of RA, especially ACPA positive Limit alcohol in patients on MTX
 Red meat	↑ Risk of gout	↑ Risk of RA with high red meat consumption
 Fish and fish oils	Shellfish ↑ risk of gout	Oily fish high in omega-3 fatty acids ↓ risk of RA, improve disease activity, reduce NSAID requirement, ↓ CVD risk
 Dairy	Low-fat dairy ↓ risk of gout	
 Fruit and vegetables	Fructose ↑ risk of gout Cherries ↓ SU	
 Healthy oils and fats		Omega-3 fats improve disease control
 Tea, coffee, and water	Coffee ↓ risk of gout Water ↓ attacks of gout	Coffee ↑ risk of RA Tea ↓ risk of RA
 Vitamin D		↓ or no risk of developing RA, may have beneficial effects on disease activity
 Antioxidants (vitamin C, vitamin E, β-carotene, selenium)	Vit C supplementation ↓ risk of gout Vit C ↓ SU	May ↑ risk RA Low vitamin C intake assoc. ↑ risk RA, no effect on disease activity Vitamin E no association with onset RA, no effect on disease activity
 Obesity	↑ BMI assoc. with ↑ risk of gout Weight loss may ↓ SU	± Risk of RA

Figure 68-3 Summary of nutrition in rheumatic diseases. BMI, body mass index; ACPA, anticitrullinated protein antibody; CVD, cardiovascular disease; MTX, methotrexate; NSAID, nonsteroidal anti-inflammatory drug; RA, rheumatoid arthritis; SU, serum urate.

Table 68-2 Comparison between NSAIDs and Anti-inflammatory Doses of Fish Oil

	NSAIDs	Fish Oil
COX inhibition	COX-1/COX-2 selectivity varies depending on agents	Nonselective
NSAID sparing	No	Yes (↓ prostaglandin E ₂)
Serious cardiovascular events	Increased (except naproxen)	Reduced
Blood pressure	Increased	Reduced
TNF and IL-1 β	Increased	Reduced
Upper gastrointestinal bleeding	Increased	Not reported
Mortality	Increased	Reduced (especially sudden cardiac death)
Time to effect	Prompt	Delayed (≤ 3 mo)

COX, cyclooxygenase; IL-1 β , interleukin-1 β ; NSAID, nonsteroidal anti-inflammatory drug; TNF, tumor necrosis factor.

The vascular benefits of omega-3 fatty acids are important in RA patients because they have an increased risk of cardiovascular disease.

Some dietary variables may interact with methotrexate.

Dietary n-3 Fatty Acids in the Management of Rheumatoid Arthritis

Fish oil is a rich source of the anti-inflammatory long-chain n-3 fatty acids EPA and DHA. The threshold dose of EPA and DHA usually required to obtain an anti-inflammatory effect is 2.7 g/day of EPA plus DHA, which is the equivalent of 9 or more standard 1-g fish oil capsules or 10 mL of bottled fish oil per day. This dose is generally more than that with which patients will self-prescribe, although community awareness of required doses varies. Tissue levels of EPA and DHA from fish and fish oils are increased when dietary n-6 fatty acid intake is reduced concomitantly through substitution of n-6 rich visible fats (e.g., with a base of corn oil, soy oil, sunflower oil) with unsaturated products with less n-6 fat (with a base of olive oil, rapeseed/canola oil, or flaxseed oil).⁸³

In general, patients with recent-onset or more established RA can be expected to achieve better disease control when anti-inflammatory doses of fish oil are co-administered with appropriately intensive combination disease-modifying antirheumatic drug (DMARD) therapy. In a longitudinal cohort study of patients with recent-onset RA (<12 months' duration), response-driven, intensive combination DMARD therapy was combined with either supplemental fish oil or placebo. At 3 years, those patients compliant with fish oil therapy had improved self-reported function in activities of daily living, lower tender joint counts, lower erythrocyte sedimentation rate (ESR), higher remission rates (72% vs. 31%), and less NSAID use than those who did not consume fish oil.⁸⁴ The better outcome for patients taking fish oil is consistent with randomized controlled trial data showing reduced symptoms with fish oil compared with placebo treatment. This study also demonstrates the feasibility of long-term fish oil use, in this case more than 3 years. Although fish oil usage may identify more compliant patients, overall DMARD usage was similar in the two groups.

Anti-inflammatory doses of fish oil have been shown to reduce NSAID requirements in patients with RA in other studies.^{85,86} NSAIDs alter the balance of PGE₂/TXA₂ in favor of TXA₂, thereby increasing the production of IL-1 β

and TNF by monocytes.⁸⁷ By contrast, fish oil has been shown to reduce the production of these cytokines.¹² Fish oil also lacks many of the adverse effects associated with NSAIDs (Table 68-2). The direct effects of fish oil and their influence on NSAID use may potentially reduce long-term tissue damage associated with release of these cytokines, although this remains to be established.

Important for both patients and physicians to recognize is that, as with most standard DMARDs, there is a latent period of up to 15 weeks before the symptomatic benefits of anti-inflammatory doses of fish oil are experienced. One small pilot study has shown that this latent period can be reduced with intravenous administration of n-3 fats.⁸⁸ Although the inconvenience and cost of intravenous therapy is a barrier to this approach, the benefits of short-term intravenous therapy can be prolonged by a switch to oral n-3 supplementation.⁸⁹

Adverse Effects of Fish Oils. The most common adverse effects associated with fish oil in anti-inflammatory doses are a fishy aftertaste, gastrointestinal upset, and nausea. These side effects are clearly neither organ nor life-threatening, but they can be dose limiting. Patient preferences vary, but in general bottled fish oil layered on juice is the most efficient way of taking an anti-inflammatory dose (one quick swallow compared with 10 to 15 standard fish oil capsules). Fish oil is best tolerated with food and not on an empty stomach. The term *fish oil* defines oil prepared from fish bodies in order to provide a distinction from cod liver oil, which is prepared from fish livers and is rich in the fat-soluble vitamins A and D. Standard fish oil contains more EPA plus DHA (30% w/w) than cod liver oil (EPA plus DHA \approx 20%) and is the preferred material. Vitamin D can be given separately as needed, and vitamin A supplementation is best avoided because negative effects on bone mineral density and fracture risk have been reported.⁹⁰

Although anti-inflammatory doses of fish oil have not been associated with serious toxicity, concerns may be raised. One consideration is a putative bleeding tendency associated with therapeutic fish oil ingestion. This notion has its origins in studies of Greenland Eskimos consuming their aboriginal diet, in whom myocardial infarction is rare and bleeding times were prolonged relative to those observed in Danes.⁹¹ However, these concerns need to be placed within the context of the high amounts of EPA and DHA in the aboriginal Eskimo diet (more than double the threshold anti-inflammatory dose) and the lower amounts of antagonistic n-6 fatty acids compared with Western diets. Although bleeding episodes have not been a feature of long-term fish oil therapy for RA⁸⁴ and platelet EPA is fourfold

lower than found in the Eskimos, surgeons may ask that fish oil be discontinued before elective surgery. Also, pharmacists may advise patients to discontinue fish oil while taking warfarin, even though no increase in bleeding tendency has been seen in patients undergoing cardiac surgery when taking fish oil concomitantly with either warfarin or aspirin therapy.⁹²

Another concern is the possible presence of the environmental contaminants methylmercury, polychlorinated biphenyls (PCBs), and dioxins, which are concentrated in large carnivorous fish. These toxins are excluded from properly prepared fish oil for therapeutic use. The FDA has accorded “generally regarded as safe” status to intakes of up to 3 g/day of long-chain n-3 fatty acids from marine sources.

Role of Omega-3 Supplementation in Rheumatic Diseases with Increased Cardiovascular Disease Risk. A number of rheumatic diseases including RA, SLE, gout, and psoriatic arthritis are associated with increased cardiovascular mortality. n-3 Fatty acid supplementation has been shown to be beneficial in the primary and secondary prevention of ischemic heart disease, as well as in heart failure.⁹³ The potential mechanisms by which n-3 fatty acids reduce cardiovascular risk include stabilization of the myocardium leading to reduction in cardiac arrhythmias, reduced blood pressure, stabilization of atheromatous plaques, reduced triglycerides and increased high-density lipoprotein (HDL), decreased platelet thromboxane release, increased vascular prostacyclin release, and anti-inflammatory effects (Figure 68-4).

To date there have been no specific studies of the cardiovascular benefits of n-3 fatty acid supplementation in patients with RA or other rheumatic diseases. However,

patients with early RA receiving fish oil have been shown to have lower triglycerides, increased “good” HDL cholesterol, less NSAID use, greater disease suppression, and reduced platelet synthesis of TXA₂, all of which can be expected to reduce cardiovascular risk.⁸⁴

Antioxidants in the Management of Rheumatoid Arthritis

Despite the association between ROS and RA, a recent meta-analysis shows no convincing evidence that antioxidant supplementation improves disease control in RA.⁹⁴

Vitamin E. Serum concentrations of vitamin E are similar in patients with RA and healthy controls.⁹⁵ A 12-week placebo-controlled study of vitamin E supplementation reported a reduction in pain scores but no effect on joint tenderness score, duration of morning stiffness, swollen joint count, or laboratory parameters.⁹⁶

Vitamin C. Although animal models have shown benefits with vitamin C supplementation, human studies have not shown any clinical benefit in patients with RA.⁹⁷

Selenium. Although not an antioxidant per se, selenium is found at the active site of the enzyme glutathione peroxidase, an important antioxidant enzyme. Plasma concentrations of selenium are reduced in patients with RA compared with healthy controls,⁹⁸ and an inverse association between serum selenium concentrations and the number of active joints has been reported.⁹⁹ Notwithstanding, studies of selenium supplementation have not shown clinical benefit in RA, despite increases in serum and red blood cell selenium concentrations.^{100,101} However, polymorphonuclear cell selenium concentrations do not increase

Figure 68-4 Effects of omega-3 fatty acids on the cardiovascular system. HDL, high-density lipoprotein; IL-1, interleukin-1; LDL, low-density lipoprotein; TNF, tumor necrosis factor; TXA₂, thromboxane A₂; VLDL, very low density lipoprotein.

with dietary supplementation, which may explain the lack of clinical effect.¹⁰²

Vitamin D and the Management of Rheumatoid Arthritis

Animal models have shown that 1,25(OH)₂D can prevent and have therapeutic benefits in experimental arthritis.¹⁰³ Studies examining the relationship between serum vitamin D concentrations and disease activity in RA have been conflicting with both an inverse relationship¹⁰⁴ and no relationship¹⁰⁵ observed.

In humans the vitamin D receptor has been shown to be expressed at sites of cartilage erosion and in chondrocytes and synoviocytes in patients with RA but not normal controls, suggesting that vitamin D may have local effects within the inflamed joint.¹⁰⁶ Supplemental vitamin D is usually prescribed to patients with RA for treatment or prophylaxis of osteoporosis. However, a 12-month trial of vitamin D (calciferol) 100,000 IU/day showed improvement in RA disease activity and reduction in the requirement for analgesics and NSAIDs.¹⁰⁷ In another small study of 19 patients with RA, oral α -calcitriol 2 μ g/day was reported to have a beneficial effect on disease activity compared with placebo.¹⁰⁸ There were neither significant side effects nor increases in serum calcium in either of these studies.

It is important to recognize that cod liver oil, a rich source of dietary n-3 fatty acids, is also rich in vitamin D. Cod liver oil has been used in the management of RA in sufficient doses to deliver anti-inflammatory doses of long chain n-3 fatty acids.¹⁰⁹ Although serum vitamin D concentrations rose significantly, the study did not allow for the respective contributions of vitamin D and co-ingested n-3 fatty acids to be evaluated. The relatively high content of vitamin A in cod liver oil militates against its use for delivering anti-inflammatory doses of n-3 fatty acids.

Dietary Restriction in Rheumatoid Arthritis—Fasting, Vegetarian, and Elimination Diets

A number of studies have examined elimination of different nutrients from the diet in the management of RA. At the extreme, total fasting and subtotal fasting reduced clinical and laboratory parameters of disease activity in some patients within a few days, but deterioration occurred on reintroduction of food.¹¹⁰ Thus fasting is an impractical management strategy because it should last no longer than 7 days and the positive effects are short-lived, whereas RA is a chronic disease. A number of potential mechanisms for this improvement have been postulated including a psychologic or placebo effect, weight loss, and immunosuppression as a result of reduced caloric intake, alteration in fatty acids, and IL-6 concentrations and alterations in gut flora.

Elemental diets aim to provide major food groups as simpler components (e.g., protein as free amino acids, fat as medium chain triglycerides, carbohydrates as small sugars). Minimal general benefit was seen in only a minority of patients with lack of benefit observed in objective parameters such as inflammatory markers, swollen, and tender joint counts.^{111,112}

Vegetarian and vegan diets have also been trialed in RA. Response to these diets has been variable with poor compliance and high dropout rates due to both lack of efficacy and adverse effects (mainly nausea and vomiting).^{113,114} More recently, a meta-analysis of four clinical trials of fasting, followed by vegetarian diets which lasted at least 3 months, showed clinically significant long-term benefits in RA can occur.¹¹⁵ However, the diet required is strict and there are no means currently to predict which patients will respond.

Elimination diets involve avoidance of foods that are putatively allergenic. Foods are deemed to be “allergenic” if their elimination results in decreased disease activity and subsequent ingestion results in increased disease activity. Although such diets may result in improvement in a proportion of patients, variable responsiveness and compliance can be a significant limitation.^{116,117} Notwithstanding, from a practical perspective, if a patient believes their arthritis is due to hypersensitivity to a particular food item or group, it may be worth assessing the effects of dietary avoidance in an $n = 1$ study of sequential withdrawal and challenge. Objective clinical and laboratory signs of disease activity should be documented after one or more cycles of withdrawal and reintroduction of the suspected food item. The findings can then be used as a basis for deciding whether the food item should be avoided by the individual in the longer term.

Interactions between Diet and Disease-Modifying Antirheumatic Drugs

It is well recognized that certain dietary components may interact with DMARDs. Methotrexate remains the anchor drug in the management of RA and is also used commonly in many other rheumatic diseases. Alcohol may increase the risk of hepatotoxicity in patients receiving methotrexate, and alcohol intake should be moderate at most. Methotrexate has multiple potential actions, many of which can be traced to its action as a dihydrofolate reductase antagonist. Routine supplementation with folic acid is recommended to reduce potential adverse effects associated with methotrexate.¹¹⁸ However, higher red blood cell folate concentrations have been associated with higher disease activity in RA patients receiving methotrexate.¹¹⁹ In some countries fortification of flour, pasta, rice, and bread with folic acid is a governmental requirement. Not surprisingly, such dietary fortification may lead to increased methotrexate doses in some patients.¹²⁰

Methotrexate treatment has been shown to increase extracellular accumulation of adenosine, which has multiple anti-inflammatory effects on neutrophils and macrophages including inhibition of IL-1 β and TNF synthesis. Caffeine is a methylxanthine and acts as an adenosine receptor antagonist. Caffeine may therefore interfere with the effects of methotrexate. In rat adjuvant arthritis, caffeine reversed the anti-inflammatory effects of methotrexate.¹²¹ In patients with RA, less intense caffeine intakes have been shown to have no effect on methotrexate efficacy¹²² or, at lower mean dose of methotrexate, to impair efficacy in caffeine doses greater than 180 mg/day compared with doses less than 120 mg/day.¹²³

Gout

KEY POINTS

Dietary interventions in gout need to address the association between gout and the metabolic syndrome and increased cardiovascular disease.

Dehydration is a trigger for acute gout.

Weight loss may reduce serum urate.

Sustained reduction of SU to less than 6 mg/dL is critical for the effective management of gout. This is generally achieved through a combination of urate-lowering therapy and dietary/lifestyle modifications. When considering dietary interventions in the management of gout, it is important to recognize that gout is associated with the metabolic syndrome and with an increased risk of cardiovascular disease and mortality.

The diet usually advocated for gout entails restricted intake of foods and drinks that contain higher amounts of purines or that are thought to precipitate acute attacks of gout. Restricted items include meat, seafood, beer/wine, and legumes. Such diets are frequently high in saturated fats and carbohydrates, which may add to the risk of metabolic syndrome.

Dehydration is a potential trigger for acute gout attacks, and increased water intake has been associated with a reduced risk of gouty attacks.¹²⁴ In a small short-term study in healthy volunteers, ingestion of cherries reduced serum urate (before urate 3.6 ± 0.2 mg/dL vs. after urate 3.1 ± 0.25 mg/dL; $P < 0.05$) and increased urinary urate excretion.¹²⁵ Whether the same effects are observed in patients with gout remains to be determined.

Vitamin C supplementation reduces SU concentrations.^{126,127} In a study of 184 patients randomized to placebo or vitamin C 500 mg/day for 2 months, SU was reduced significantly in the vitamin C group with a mean reduction of -0.5 mg/dL (95% CI, -0.5 to 0.02 mg/dL) compared with the placebo group ($P < 0.0001$).¹²⁸ In the subgroup of 21 patients with baseline SU greater than 7 mg/dL, the mean reduction in serum urate was 1.3 mg/dL. This reduction in SU suggests vitamin C is a possible additional therapy for patients with gout and persistent hyperuricemia.

In obese patients weight loss may reduce SU,^{129,130} as well as provide other health benefits. In one study, 13 males with gout lost weight over 16 weeks (pre BMI, 30.5 ± 8.1 kg/m²; post BMI, 27.8 ± 7.9 kg/m²). SU decreased in all subjects; pre SU, 9.6 ± 1.7 mg/dL versus post SU, 7.9 ± 1.5 mg/dL; $P = 0.001$. A decrease in frequency of gouty attacks was seen from 2.1 ± 0.8 attacks/month to 0.6 ± 0.7 attacks/month ($P = 0.002$).¹³¹ However, not all studies have shown a reduction in SU with weight loss.¹³²

Osteoarthritis

KEY POINTS

Weight loss is important in the management of OA.

From a mechanistic viewpoint n-3 fatty acids may be beneficial and can be an alternative or adjunct to NSAIDs for long-term analgesia.

Weight loss is generally considered an important aspect in the management of OA of weight-bearing joints. A recent meta-analysis of weight loss studies in patients with knee OA reported that moderate weight loss ($\geq 5\%$) is associated with statistically significant improvement in self-reported disability scores. Although knee pain was also reduced, this did not reach statistical significance.¹³³

n-3 Fatty acids have recently been shown to reduce IL-1 α -induced expression of the degradative enzymes such as MMP-3, MMP-13, and ADAMTs in bovine chondrocyte cultures, suggesting that n-3 supplementation may be beneficial in OA.¹⁰ Results of suitably powered studies of fish oil in OA are awaited.

Probiotics in the Management of Rheumatic Diseases

KEY POINT

There are insufficient data to support routine use of probiotics in inflammatory rheumatic diseases.

Although most interest has focused on the role of probiotics in inflammatory bowel diseases, there are a number of studies in animal models of arthritis, as well as human studies in RA and spondyloarthritis.

Probiotics have been reported to enhance the antiarthritic effects of methotrexate in adjuvant-induced arthritis in rats,^{134,135} whereas in collagen-induced arthritis probiotics downregulated Th1 effector cells, leading to suppression of joint inflammation and reduction in cartilage destruction.¹³⁶

In studies of patients with rheumatic diseases, results have varied depending on the probiotic administered. In a study of 21 patients with RA, 12 months' supplementation with *Lactobacillus rhamnosus* had no effect on disease activity.¹³⁷ In 63 patients with active spondyloarthritis, there was no difference in outcomes after 12 weeks of probiotic supplement containing *Streptococcus salivarius*, *Bifidobacterium lactus*, and *Lactobacillus acidophilus* compared with placebo.¹³⁸ By contrast, in a 60-day study of 45 patients with RA, improvement in pain and patient global scores were seen with *Bacillus coagulans* GBI-30 supplements compared with placebo.¹³⁹

Alterations in gut microbial flora may also influence absorption and metabolism of drugs. Of particular importance for patients with rheumatic diseases are potential effects on DMARDs, especially salazopyrin, which is metabolized to the active metabolites sulfapyridine and 5-aminosalicylic acid by intestinal microbes. Probiotics that alter intestinal microflora may potentially alter efficacy and toxicity of salazopyrin. Although alterations in salazopyrin metabolism with probiotic supplements have been demonstrated in an animal model, similar effects were not observed in a human study.¹⁴⁰

In summary, although theoretic considerations and empiric data provide some support for use of probiotics in RA, the evidence is not sufficient to recommend routine use.

CONCLUSIONS

Rheumatic diseases are typically chronic, and, as with any chronic disease, nutritional issues are intrinsic to optimization of long-term health. Although patients as individuals can make their own nutritional choices, it behooves rheumatologists to be adequately informed regarding the plausibility and evidence for frequently considered nutritional supplements, toward which this chapter has been directed. In terms of positive advice for patients and referring physicians, the strongest case can be made for dietary supplementation with fish oil in adequate doses. For long-term analgesia in rheumatic diseases, fish oil can be recommended in favor of NSAIDs. To the extent that fish oil is taken instead of NSAIDs, the risks for serious upper gastrointestinal complications and increased risk for serious thrombotic cardiovascular events associated with NSAIDs will be avoided because fish oil has not been associated with these risks. Furthermore, fish oil has been shown to reduce cardiovascular risks through mechanisms independent of and additional to its NSAID-sparing effects.

Etiology and Pathogenesis of Rheumatoid Arthritis

GARY S. FIRESTEIN

KEY POINTS

Rheumatoid arthritis (RA) is a complex disease involving numerous cell types, including macrophages, T cells, B cells, fibroblasts, chondrocytes, neutrophils, mast cells, and dendritic cells.

Several genes are implicated in susceptibility to RA and severity of disease, including class II major histocompatibility complex genes, *PTPN22*, and peptidylarginine deiminases.

Evidence of autoimmunity, including high serum levels of autoantibodies such as rheumatoid factors and anticitrullinated protein antibodies, can be present for many years before the onset of clinical arthritis.

Adaptive and innate immune responses in the synovium have been implicated in the pathogenesis of RA.

Cytokine networks involving tumor necrosis factor, interleukin-6, and many other factors participate in disease perpetuation and can be targeted by therapeutic agents.

Bone and cartilage destruction are primarily mediated by osteoclasts and fibroblast-like synoviocytes, respectively.

Rheumatoid arthritis (RA) is the most common inflammatory arthritis, affecting from 0.5% to 1% of the general population worldwide. Although the prevalence is surprisingly constant across the globe, regardless of geographic location and race, there are some exceptions. For instance, in China the occurrence of RA is somewhat lower ($\approx 0.3\%$), whereas it is substantially higher in other groups such as the Pima Indians in North America ($\approx 5\%$). Because of its prevalence and the ready accessibility of joint samples for laboratory investigation, RA has served as a useful model for the study of all inflammatory and immune-mediated diseases. As such, the information gleaned from these studies provides new and unique insights into the mechanisms of normal immunity.

Although RA is primarily considered a disease of the joints, abnormal systemic immune responses are evident and can cause a variety of extra-articular manifestations. These manifestations clearly show that RA has features of a systemic disease that can involve many organs. In some cases, autoantibody production with the formation of

immune complexes that fix complement contribute to these extra-articular findings. One of the mysteries of RA is why the synovium is the primary target, although the unique structure of its vascular bed could provide an environment that is ideal for innate and adaptive immune responses.

Although the precise causes of RA remain uncertain, environmental and genetic influences clearly participate. Clues have been provided by detailed immunogenetic studies and the observation that underlying autoimmunity antedates onset of arthritis by up to a decade. Progress in understanding the pathogenesis has been even more robust: The roles of small-molecule mediators of inflammation (e.g., arachidonic acid metabolites), autoantibodies, cytokines, growth factors, chemokines, adhesion molecules, and matrix metalloproteinases (MMPs) have been carefully defined. Synovial cells can exhibit behavior resembling a localized tumor that invades and destroys articular cartilage, subchondral bone, tendons, and ligaments. Irreversible loss of articular cartilage and bone begins soon after the onset of RA, and early interventions can probably improve long-term outcomes. Increased appreciation of how comorbidities, especially cardiovascular disease and accelerated atherosclerosis, can affect mortality has also led to attempts to suppress synovial and systemic inflammation.

ETIOLOGY AND PATHOGENESIS OF RHEUMATOID ARTHRITIS: ROLES OF INNATE AND ADAPTIVE IMMUNITY

The etiology and pathogenesis of RA are complex and multifaceted. A variety of predetermined (genes) and stochastic (random events and environment) factors contribute to susceptibility and pathogenesis. As an introduction, a summary of how these mechanisms interact to create and perpetuate RA is shown in [Figure 69-1](#). Individual mechanisms are discussed in greater detail throughout the chapter.

The initiation of RA probably begins years before the onset of clinical symptoms. This process involves certain specific genes that can help break tolerance and lead to autoreactivity. It is likely that the earliest phases are marked by repeated activation of innate immunity (see [Figure](#)

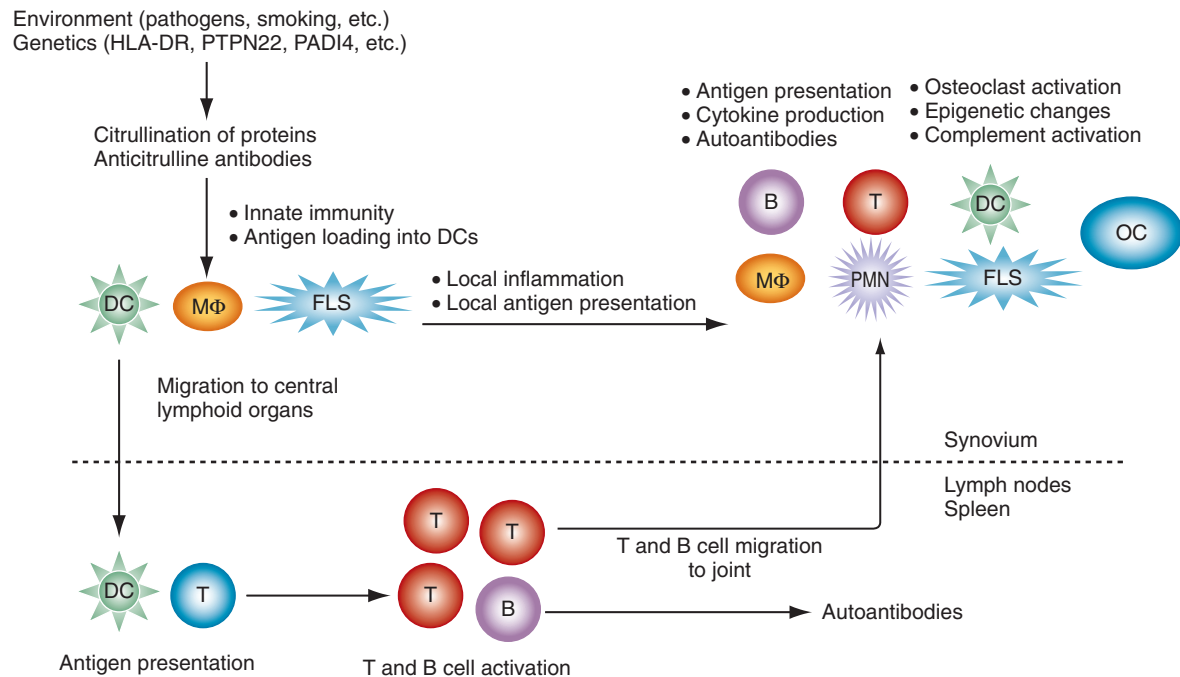

Figure 69-1 Schematic diagram of disease mechanisms that likely occur in rheumatoid arthritis. Innate immunity could activate fibroblast-like synoviocytes (FLS), dendritic cells (DC), and macrophages (MΦ) in the earliest phases in individuals with underlying immune hyper-reactivity as evidenced by the production of autoantibodies. The genetic makeup of an individual including the presence of certain gene polymorphisms in genes that regulate immune responses and environmental exposures are both required. Chronic inflammation leads to citrullination of proteins in a variety of sites including mucosal surfaces such as the lungs or the joint. In a genetically susceptible individual, a breakdown of tolerance can occur with the formation of anticitrullinated protein antibodies. DCs can migrate to the central lymphoid organs to present antigen and activate T cells, which can in turn activate B cells. These lymphocytes can migrate back to the synovium and enhance adaptive immune responses in the target organ. In addition, repeated activation of innate immunity can directly lead to chronic inflammation and possibly antigen presentation in the synovium. In the latter phases of disease, many cell types activate osteoclasts (OC) through the receptor activator of nuclear factor κ B (NF κ B)/receptor activator of NF κ B ligand (RANK/RANKL) system, although FLS and T cells likely provide the greatest stimulus. Autonomous activation of FLS might also contribute to this process.

69-1).¹ Cigarette smoke, bacterial products, viral components, and other environmental stimuli can contribute to these responses. This process probably occurs often in normal individuals but is self-limited. In individuals, a pre-determined propensity for immune hyper-reactivity or auto-reactivity might lead to a different outcome. The genome of these individuals might encode for a variety of genes implicated in RA including class II major histocompatibility complex (MHC) genes, protein tyrosine phosphatase-22 (PTPN22), cytokine promoter polymorphisms, signal transduction gene polymorphisms, population-specific genes (e.g., *PADI4* in Japanese or Koreans), and other undefined genes. Abnormal T cell selection could also contribute by allowing autoreactive T cells to escape deletion. The environmental stresses can lead to post-transcriptional modification of proteins, especially citrullination of arginine residues, in mucosal surfaces or the synovium. Although this commonly occurs without sequelae in normal individuals, people with a propensity for RA can develop antibodies against these modified proteins with production of rheumatoid factors (RFs) and anticitrullinated protein antibodies (ACPAs).

Activation of synovial innate immunity can also increase vascular leakage in the synovium, production of chemoattractants that recruit immune cells to the joint, and processing of antigens by dendritic cells. Antigen presentation can potentially occur in the synovial germinal centers or, more

commonly, in central lymphoid organs after the loaded dendritic cells migrate via the lymphatics. Naïve T cells can then be activated through interactions with the T cell receptor and co-stimulatory signals. T cells can help B cells produce pathogenic antibodies and/or migrate to the joint, where they can influence other cells through the production of cytokines such as interleukin (IL)-17 or through cell contact mechanisms that do not require a specific antigen. Although it is uncertain what transforms subclinical inflammation to symptomatic arthritis, this process can take up to a decade before it reaches fruition.

Ultimately, a destructive phase proceeds, which can have antigen-dependent and -independent mechanisms and is mediated by mesenchymal elements such as fibroblasts and synoviocytes. Bone erosions are subsequently caused by osteoclasts, whereas cartilage dissolution results from proteolytic enzymes produced by synoviocytes in the pannus or synovial fluid neutrophils. Anti-inflammatory mechanisms such as soluble TNF receptors, suppressive cytokines, cytokine binding proteins, protease inhibitors, lipoxins, antioxidants, antiangiogenic factors, and natural cytokine antagonists are not present in sufficient concentrations to truncate the inflammatory and destructive process. The only way to suppress this response is through therapeutic interventions that either modulate pathogenic cells or neutralize the effector molecules produced by the rheumatoid process, or restore tolerance.

The heterogeneity of mechanisms provides an explanation for the unpredictable response to therapeutic agents and also allows clinicians to consider new therapeutic targets to either prevent RA or interfere with the immunologic, inflammatory, or destructive components as separate but interrelated entities. Each of these mechanisms is discussed in detail later. Brief summaries are also provided intermittently to help guide the reader through this complex maze.

ETIOLOGY OF RHEUMATOID ARTHRITIS

KEY POINTS

Genes play a key role in susceptibility to RA, as well as disease severity.

Class II major histocompatibility genes, especially those containing a specific 5 amino acid sequence in the hypervariable region of HLA-DR4, are the most prominent genetic association.

Newly defined genetic associations including polymorphisms in *PTPN22* and *PADI4* suggest that the associations in RA are complex and involve many genes.

Although the etiology of RA remains unknown, a variety of studies suggest that the interaction of environmental and genetic factors is responsible; either one is necessary but not sufficient for full expression of the disease. The most compelling example for a genetic component is in monozygotic twins, in whom the concordance rate is perhaps 12% to 15% when one twin is affected, compared with 1% for the general population. The fact that concordance is not higher provides key evidence that other influences such as the environment, epigenetics, or even microchimerism from maternal-fetal transfer might be as important as or even more important than the genetic component. The risk for a fraternal twin of a patient with RA is also high ($\approx 2\%$ to 5%) but similar to the rate for other first-degree relatives.

Although the immunogenetics is, at best, incompletely understood, one of the best-studied and perhaps most influential genetic risk factor is the class II MHC haplotype of an individual. *PTPN22* and *PADI4* increase risk in some racial and ethnic groups, but not all. Genome-wide screens have implicated at least 35 genes, many of which are involved with immune function. However, most have a relatively modest contribution and the susceptibility polymorphism confers only a 1.1- or 1.2-fold increase. Combinations of genes can clearly interact with one another, and a 45-fold increase in risk is conferred by a combination of HLA-DR, *PTPN22*, and the *TRAF1-C5*.¹ This combination, however, is found in less than 1% of individuals with RA. The RA-associated alleles identified to date contribute approximately 40% of total genetic susceptibility. Additional progress in understanding the role of genes in RA including rare variants that might be more important than some common polymorphisms will require sophisticated bioinformatics to clarify how individual alleles contribute to susceptibility, severity, and response to targeted therapies.

Role of HLA-DR in the Susceptibility to and Severity of Rheumatoid Arthritis

The structure of class II MHC molecules on antigen-presenting cells is associated with increased susceptibility and severity of RA and accounts for about 40% of the genetic influence. A genetic link between HLA-DR and RA was initially described in the 1970s with the observation that HLA-DR4 occurred in 70% of RA patients, compared with about 30% of controls, giving a relative risk of having RA to those with HLA-DR4 of approximately 4 to 5.

The susceptibility to RA is associated with the third hypervariable region of DR β -chains, from amino acids 70 through 74. The epitope is glutamine-leucine-arginine-alanine-alanine (QKRAA), a sequence found in DR4 and DR14, in addition to some DR1 β -chains. The “susceptibility epitope” (SE) on DR4 β -chains with the greatest association with RA are DRB*0401, DRB*0404, DRB*0101, and DRB*1402 (Table 69-1). Up to 96% of patients with RA exhibit the appropriate HLA-DR locus in some populations.² In certain ethnic and racial groups, however, the association with QKRAA is not as prominent or is not associated. The QKRAA epitope might also predict the severity of established RA, with a greater prevalence of extra-articular disease and erosions in patients with two copies. Other HLA genes such as DRB*1301 contain the DERRAA sequence and are associated with decreased susceptibility to RA.³

One intriguing possibility that could account for some patients who do not fit within this paradigm is microchimerism.⁴ Maternal cells expressing the SE can survive and persist in the circulation throughout adulthood. These non-inherited maternal antigens (NIMAs) could then confer increased risk of disease in the children of SE-expressing women.

The region associated with RA (QKRAA) primarily faces away from the antigen-binding cleft of the DR molecule that determines the specificity of peptides presented to

Table 69-1 Nomenclature for HLA-DR Alleles and Associations with Rheumatoid Arthritis

Old Nomenclature (HLA-DRB1 Alleles)	Current Nomenclature	Association with Rheumatoid Arthritis
HLA-DR1	0101	+
HLA-DR4 Dw4	0401	+
HLA-DR4 Dw14	0404/0408	+
HLA-DRw14 Dw16	1402	+
HLA-DR4 Dw10	0402	—
HLA-DR2	1501, 1502, 1601, 1602	—
HLA-DR3	0301, 0302	—
HLA-DR5	1101-1104, 1201, 1202	—
HLA-DR7	0701, 0702	—
HLA-DRw8	0801, 0803	—
HLA-DR9	0901	—
HLA-DRw10	1001	—
HLA-DRw13	1301-1304	1301 associated with protection
HLA-DRw14 Dw9	1401	—

Modified from Weyand CM, Hicok KC, Conn DL, Goronzy JJ: The influence of HLA-DRB1 genes on disease severity in rheumatoid arthritis, *Ann Intern Med* 117:801, 1992.

CD4⁺ helper T cells. Attempts to elute peptides from the binding pocket of RA-associated alleles have not revealed a specific antigen that is either unique to or associated with RA. The precise function of the SE is uncertain, but it could also play a role in shaping the T cell repertoire in the thymus or altering intracellular HLA-DR trafficking and antigen loading. QKRAA could serve as an autoantigen due to molecular mimicry in some situations because some xenoproteins such as gp110 from the Epstein-Barr virus also include this sequence.

The shared epitope might not be an independent risk factor for RA but instead a marker for immunoreactivity and anticitrullinated protein antibodies (ACPAs).⁵ In a large series of patients with early undifferentiated inflammatory arthritis, one-third of patients met criteria for RA within 1 year. Progress to RA occurred regardless of HLA-DR genotype if patients were anticitrullinated protein (anti-CP) positive. When patients were stratified according to ACPA, the shared epitope did not make an additional contribution to progression from undifferentiated arthritis to RA. The shared epitope probably contributes to immune hyper-reactivity, but ACPAs are more closely associated with RA. In other studies, however, the presence of the shared epitope and ACPAs together is associated with even greater disease severity.

Additional Polymorphisms: Cytokines, Citrullinating Enzymes, *PTPN22*, and Others

The genetic influence on RA has also led to studies evaluating non-MHC genes. Single nucleotide polymorphisms (SNPs) in promoter regions, coding regions, or areas with no known function have been extensively investigated in RA with a variety of methods including genome-wide association studies. Table 69-2 shows some of the SNPs and microsatellites that have been associated with RA. The relative contribution for most is modest, and variations in technique, stage of disease, and patient populations result in some disagreement among various reports.

Given the importance of cytokines in RA (see following), it is not surprising that many studies have focused on these genes. The most intriguing evidence relates to tumor necrosis factor (TNF). This proinflammatory factor is a major cytokine in the pathogenesis of RA, and the TNF genes are located in the MHC locus on chromosome 6 in humans. Several polymorphisms of the TNF promoter including two at positions -238 and -308 can alter gene

transcription. Associations among the TNF polymorphisms and RA susceptibility and radiographic progression have been reported, although there is not uniform agreement. In addition, certain polymorphisms in cytokines, especially TNF or Fc receptors, have been associated with differential response to therapy. For instance, substitution of a T for a C at position -857 in the TNF promoter might confer greater responsiveness to TNF inhibitors.⁶

Among the many noncytokine and non-MHC genetic linkages described for RA, the ones associated with peptidyl arginase deiminase (*PADI*) and *PTPN22* have the strongest effect on susceptibility. The *PADI* genes are responsible for the post-translational modification of arginine to citrulline. Four isoforms have been identified, known as *PADI1* through *PADI4*. In light of the striking associations of RA with ACPAs, several groups have investigated potential associations with these genes. The most promising is an extended haplotype in the *PADI4* gene that can lead to increased levels of *PADI4* protein due to enhanced messenger RNA (mRNA) stability.⁷ In a Japanese cohort, a twofold increase in risk of RA was observed with *PADI4* SNPs. Confirmatory reports have been mixed because the association has been confirmed in other Asian populations but not in Western Europe. These studies suggest that the contribution of *PADI4* to RA might be restricted, depending on the overall genetic background of the patient population.

Protein tyrosine phosphatase-22 (*PTPN22*) associations have been discovered in large-scale screening efforts to identify SNP associations in RA.⁸ Using 12,000 SNPs in the initial screens, a novel association was discovered at position 1858 in the *PTPN22* gene that, like *PADI4*, conferred a twofold increase in risk. The allele containing thymidine leading to an amino acid substitution (R620W) was present in 8.5% of controls but was found in nearly 15% in patients with seropositive RA. Subsequent studies have demonstrated a similar association with systemic lupus erythematosus (SLE), type 1 diabetes, and several other autoimmune diseases. *PTPN22* is a phosphatase that regulates the phosphorylation status of several kinases important to T cell activation including Lck and ZAP70. The R620W allele surprisingly results in a gain of function that alters the threshold for T cell receptor (TCR) signaling. Because the *PTPN22* allele is rare in Japan, it is another gene (e.g., *PADI4*) where susceptibility is specific for particular ethnic or racial populations.

The list of genes associated with RA consistently involves immune regulation.⁹ Cytokine polymorphisms such as for TNF and the IL-1 inhibitor, IL-1Ra are not surprising. Genes that regulate adaptive immune responses in T cells such as *PTPN22* and the co-stimulation receptor CTLA have also been associated with RA. Other genes associated with B cell function and/or antigen presentation such as *BTLA* (B- and T-lymphocyte attenuator), Fc receptors, and *CD40* are also implicated. Polymorphisms have also been identified in signal transduction pathways that regulate immune function such as *TRAF1-C5* and *STAT4*. The consistent thread in this analysis is that most gene associations for RA cluster to innate immunity, adaptive immunity, and inflammation. Aside from providing insight into the mechanisms of disease, they could also potentially contribute to responses to targeted therapies.

Table 69-2 Key Genetic Associations in Rheumatoid Arthritis

Gene	Odds Ratio for Risk Alleles	Comment
<i>HLA-DR</i>	4-5 fold	
<i>PTPN22</i>	≈2 fold	Not in Asian populations
<i>PADI4</i>	≈2 fold	Primarily in Asian populations
<i>TRAF1-C5</i>	>1.2 fold; <2 fold	
<i>STAT4</i>	>1.2 fold; <2 fold	
<i>TNFAIP3</i>	>1.2 fold; <2 fold	
<i>IL2/21</i>	>1.2 fold; <2 fold	

Other genes with odds ratio >1.0 and <1.2: *CTLA4*, *CD40*, *CCL21*, *CD244*, *IL2Rb*, *TNFRSF14*, *PRKCQ*, *PIP4K2C*, *IL2RA*, *AFF3*, *REL*, *BLK*, *TAGAP*, *CD28*, *TRAF6*, *PTPRC*, *FCGR2A*, *PRDM1*, *CD2-CD58*, *IRF5*, *CCR6*, *CCL21*, *IL6ST*, *RBPJ*.

Interactions between Genes and Environment

A number of environmental factors clearly contribute to RA susceptibility, although no specific exposure has been identified as the pivotal agent. Smoking is the best defined environmental risk factor for seropositive RA. The reason for its influence on the development of synovitis is not fully defined but could involve the activation of innate immunity and *PADI* in the airway. Citrullinated proteins have been detected in bronchoalveolar lavage samples of smokers, and this could provide a stimulus for generation of ACPAs in susceptible individuals.¹⁰ Repeated activation of innate immunity, especially in an individual with underlying genetically determined autoreactivity, could potentially contribute to autoreactivity and the initiation of synovitis. Other environmental factors such as oral contraceptives appear to modestly protect from RA, perhaps due to changes in the hormone milieu.¹¹

The interaction between HLA-DR and tobacco exposure is perhaps the best example of how genes and the environment conspire to enhance risk. Although smoking and the SE alone modestly increase the likelihood of developing RA, the combination is synergistic.¹² An individual with a history of cigarette smoking and two copies of the SE increases the odds of developing RA by up to 40-fold. The mechanism of the interaction is not known, but it could potentially relate to the increase in protein citrullination in smokers and increased ability of SE-containing HLA-DR molecules to bind some citrullinated proteins. The extent of smoking is also predictive, with the greatest risk seen with at least 20 pack-years. The risk declines slowly with cessation of smoking, taking more than a decade to begin approaching nonsmokers.¹³ Alcohol consumption can decrease this risk, and exposure to other inhaled irritants like silica dust increases risk, demonstrating the complexity of environment and human behavior on understanding disease susceptibility.

Gender

RA is one of many chronic autoimmune diseases that predominates in women. The ratio of female-to-male patients is 2:1 to 3:1, which is not as high as Hashimoto's thyroiditis (25:1 to 50:1) or SLE (9:1). The gender effect is often observed in some animal models of autoimmunity such as the NZB/NZW model of SLE, in which female mice have more severe disease. Estrogens are one obvious explanation, and some data support the concept that these hormones modulate immune function.¹⁴ For example, autoantibody-producing B cells exposed to estradiol are more resistant to apoptosis, suggesting that autoreactive B cell clones might escape tolerance. The effect on T lymphocytes is harder to reconcile with the female preponderance in RA because estrogens tend to bias T cell differentiation toward the Th2 phenotype. The cytokines produced by this subset such as IL-4 and IL-13 are usually considered anti-inflammatory in animal models of arthritis and are present in only limited amounts in the RA synovium. Estrogen receptors are expressed on fibroblast-like synoviocytes (FLS) and increase production of metalloproteinases. In macrophage cell lines, estrogen can enhance production of TNF. Nulliparity has also been suggested as a risk factor in early studies, but more

recent reports do not support this notion. Thus the effects of estrogens are complex, and the specific mechanisms responsible for the female preponderance of RA are not fully understood.

Pregnancy is often associated with remission of the disease in the last trimester. More than three quarters of pregnant patients with RA improve in the first or second trimester, but 90% of these experience a flare of disease associated with a rise in RF titers in the weeks or months after delivery. The mechanism of protection is not defined but might be due to the expression of suppressive cytokines such as IL-10 during pregnancy, production of α -fetoprotein, or alterations in cell-mediated immunity. One intriguing finding is that fetal DNA levels in the maternal peripheral blood correlate with the propensity for improved symptoms in pregnant RA patients. It is not certain whether the DNA itself contributes or whether it is a marker for increased leakage of fetal cells into the maternal circulation.¹⁵ Immune responses directed against paternal HLA antigens can occur and lead to the production of alloantibodies in the maternal circulation. Maternal-fetal disparity in human leukocyte antigen (HLA) class II phenotypes can correlate with pregnancy-induced remission. More than three-fourths of pregnant women with maternal-fetal disparity of HLA-DRB1, DQA, and DQB haplotypes have significant improvement, whereas disparity is only observed in one-fourth of women whose pregnancy is characterized by continuous active arthritis.¹⁶ Therefore suppression of maternal immune responses to paternal HLA haplotypes might be protective. This question remains unsettled because another study failed to find a correlation between the HLA disparity and clinical improvement during pregnancy.¹⁷

Epigenetics

Epigenetics describes phenotypic or gene expression properties caused by mechanisms other than changes in the underlying DNA sequence. Modification of CpG DNA sequences by methylation, for example, can suppress gene expression, and it plays a role in cell differentiation. Histone acetylation also alters accessibility of DNA for transcription factors and RNA polymerases. microRNAs can bind to DNA and suppress expression of key genes involved with the inflammatory process. Some epigenetic information such as DNA methylation can be transferred from one generation to the next, thereby providing an alternative mechanism for rapidly altering disease susceptibility in a population due to the environment.

Most information on epigenetics in RA comes from studies of RA synovium or cultured synoviocytes. Some evidence of imprinting is available in the latter, with evidence of global DNA hypomethylation.¹⁸ Only low levels of a key DNA methylase, *Dnmt1* are expressed in RA synovium, suggesting a molecular basis for this observation. Because this enzyme is carried by gametes, the methylation pattern can be transgenerationally maintained. One particular CpG site in the IL-6 promoter of peripheral blood mononuclear cells has decreased methylation, and this is associated with higher levels of IL-6 production.¹⁹ Dietary influences such as ingestion of methyl donors such as folate, or even exposure to methyl donors in utero, can profoundly alter DNA methylation and adaptive

immune functions and affect susceptibility to autoimmune disease.

The histone deacetylase HDAC1 is overexpressed in RA FLS. When this gene is suppressed, synovioyte proliferation decreases and expression of tumor suppressor proteins such as p53 increases. HDAC inhibitors are also effective in collagen-induced arthritis, markedly delaying the onset of disease and decreasing bone erosions. Finally, analysis of synovioytes shows that some individual microRNAs such as microRNA-124a are decreased in RA compared with osteoarthritis (OA) cells. This particular microRNA can suppress cell cycling and chemokine genes. Increasing microRNA-124a levels in RA synovioytes decreased the production of the chemokine MCP-1.²⁰ Forced expression of microRNA-203 increases metalloproteinase and IL-6 expression by synovioytes as well.²¹

The role of epigenetics in RA is not understood. It is not clear whether these observations occur before the onset of disease, are involved with the transition from asymptomatic autoimmunity to clinical disease, or participate in the destructive phase in established RA. Environmental stress plays a major role in disease susceptibility, perhaps greater than DNA polymorphisms. The mechanisms probably involve epigenetic deregulation of gene expression leading to decreased thresholds for autoreactivity in the adaptive immune system.

Changing Epidemiology of Rheumatoid Arthritis

The history of RA reveals the surprising observation that it is a relatively new disease in Europe and Northern Africa. Examination of ancient skeletal remains in Europe and Northern Africa fails to reveal convincing evidence of RA, even though other rheumatic diseases such as OA, ankylosing spondylitis, and gout are readily discernable. In contrast, typical marginal erosions and rheumatoid lesions are present in the skeletons of Native Americans found in Tennessee, Alabama, and Central America from thousands of years ago. The first clear descriptions of RA in Europe appeared in the seventeenth century, and the disease was distinguished from gout and rheumatic fever by Garrod in the mid-nineteenth century. Although still controversial, the disease might have migrated from the New World to the Old World coincident with opening the trade and exploration routes. Because genetic admixture was relatively limited, an undefined environmental exposure potentially caused RA in susceptible Europeans. The most obvious explanation would, of course, be that an infectious agent is responsible. However, other environmental influences like tobacco smoking were also introduced to the Old World at the same time and could play a role.

Equally intriguing, the severity and incidence of RA appeared to decrease in the late twentieth century (Figure 69-2).²² In certain well-defined populations including Native Americans, the incidence of RA has gradually declined by as much as 50% over the past half of the twentieth century. Changes in hygiene and other lifestyle modifications related to industrialization might contribute, and an infectious agent might be less prevalent secondary to these societal changes, as with many other infectious diseases. Recent data from 1995 to 2007 suggest that the incidence might be rising again in women, but not in men.

Figure 69-2 Population studies in Minnesota demonstrated a gradually decreasing incidence of rheumatoid arthritis from 1960 to 1990. Similar results have been observed in Native American populations. (From Doran MF, Pond GR, Crowson CS, et al: Trends in incidence and mortality in rheumatoid arthritis in Rochester, Minnesota over a forty-year period, *Arthritis Rheum* 46:625–631, 2002.)

Dissecting the environmental exposures will be key to understanding how the susceptibility to disease varies over time.²³

PATHOGENIC MECHANISMS IN RHEUMATOID ARTHRITIS

KEY POINTS

Although an etiologic link has not been established, pathogens such as viruses, retroviruses, bacteria, and mycoplasma have been associated with RA.

A single specific “RA pathogen” is unlikely.

Repeated inflammatory stress, especially through specialized receptors that recognize common molecules produced by pathogens, in a genetically susceptible individual might contribute to breakdown of tolerance and subsequent autoimmunity.

Considerable effort has been expended to assess the role of infectious agents in RA (Table 69-3). A potential pathogen could initiate disease through a variety of mechanisms including direct infection of the synovium, activation of innate immunity by pattern-recognition receptors that bind to components of the agent, or through molecular mimicry that induces an autoreactive adaptive immune response.

Infectious Agents: Direct Infection and Innate Immune Responses

Toll-like Receptors and the Inflammasome in the Joint

Infectious agents could contribute to the initiation or perpetuation of RA through a variety of mechanisms. Some arthrotropic microorganisms could potentially infect the synovium and cause a local inflammatory response. There is increasing awareness that the innate immune system could also directly affect the onset and course of synovitis.

Table 69-3 Etiology of Rheumatoid Arthritis: Possible Infectious Causes

Infectious Agent	Potential Pathogenic Mechanisms
<i>Mycoplasma</i>	Direct synovial infection; superantigens
Parvovirus B19	Direct synovial infection
Retroviruses	Direct synovial infection
Enteric bacteria	Molecular mimicry (QKRAA, e.g., in bacterial heat shock proteins)
<i>Mycobacterium</i>	Molecular mimicry (proteoglycans, QKRAA), immunostimulatory DNA (Toll-like receptor 9 activation)
Epstein-Barr virus	Molecular mimicry (QKRAA in gp110)
Bacterial cell walls	Toll-like receptor 2 activation

Pathogen-associated molecular pattern receptors, especially the Toll-like receptors (TLRs), are expressed by sentinel cells in the host that provide a first line of defense. These receptors recognize preserved structures in bacteria and other infectious agents and permit rapid release of inflammatory mediators, activation of antigen-presenting cells, and enhancement of adaptive immune responses.

At least 11 TLRs exist in humans such as TLR2 (binds peptidoglycans), TLR3 (binds double-stranded RNA [dsRNA]), TLR4 (binds lipopolysaccharide), and TLR9 (binds bacterial DNA containing CpG motifs). Many of these pattern recognition receptors are expressed by rheumatoid synovial tissue and cultured FLS including TLR2, TLR3, TLR4, and TLR9. Exogenous TLR ligands such as bacterial peptidoglycan and DNA, as well as endogenous ligands (e.g., heat shock proteins, fibrinogen, and hyaluronan), are present in arthritic joints (see later). Engagement of these receptors participates in certain animal models of arthritis and can exacerbate synovial inflammation. TLR3, which recognizes viral dsRNA and activates the antiviral response, is also expressed by synovial cells in the intimal lining. Necrotic debris containing mRNA from RA synovial fluid cells activates TLR3 signaling and proinflammatory gene expression in synovitis.

The role of innate immunity in RA led to the notion that repeated engagement of TLRs in the synovium could help initiate disease. This hypothesis could explain why specific pathogens have been difficult to identify in the joint. In contrast, a genetically susceptible individual could potentially break tolerance if the TLRs are repeatedly engaged and permit autoimmune responses against articular antigens. Several animal models of disease require TLR ligands for initiations such as TLR9 in adjuvant arthritis. TLR2 is required for streptococcal cell wall arthritis, and the chronic T cell-dependent phase of that model requires TLR4. Mice lacking TLR4^{-/-} have significantly less joint damage induced by IL-1 overexpression, even though synovial inflammation is still robust.²⁴ These data suggest that endogenous TLR ligands play a key role in matrix regulation independent of inflammatory responses.

A second mechanism that regulates innate immunity involves a novel structure called the inflammasome. This complex includes several proteins involved in recognition of “danger signals” and pathogens such as muramyl dipeptides and uric acid. One central component is cryopyrin, also called NALP3, which is linked to caspase 1 (IL-1 convertase) by adapter proteins. When the inflammasome is engaged, caspase 1 is activated and IL-1 is produced.

Mutations in this pathway, especially in cryopyrin, have been associated with autoinflammatory disorders such as Muckle-Wells syndrome and familial cold autoinflammatory disease. Inflammation induced by uric acid crystals or ATP uses this pathway and can be abrogated by IL-1 inhibitors. Cryopyrin is abundant in RA synovium and is constitutively expressed by FLS and macrophages. Expression in cultured FLS is markedly increased by TNF. Although the role of the inflammasome in RA has not been fully defined, its ability to induce cytokine production by exposure to bacterial products and other danger signals suggests that it participates in IL-1 and IL-18 regulation.

Bacteria, *Mycobacteria*, *Mycoplasma*, and Their Components

Active infection of synovial tissue by pyogenic bacteria is an unlikely cause of RA, and extensive searches for a unique or specific organism in synovial tissue or joint effusions have been negative. Antibodies to certain organisms such as *Proteus* are reportedly elevated in the blood of patients with RA, but this could represent an epiphenomenon or a non-specific B cell activation. Most RA and reactive arthritis patients contain bacterial DNA sequences in their synovium. The bacteria identified are not unique and generally represent a cross-section of skin and mucosal bacteria including *Acinetobacter* and *Bacillus* spp. It is possible that the synovium functions as an adjunct to the reticuloendothelial system in arthritis, allowing local macrophages to accumulate circulating bacterial products.

In addition to prokaryotic DNA, bacterial peptidoglycans have been detected in RA synovial tissue (Figure 69-3). Antigen-presenting cells containing these products express TLRs and produce proinflammatory cytokines such as TNF. It is not known whether the peptidoglycans activate cells in situ or whether phagocytic cells from other sites or the blood engage the molecules and then migrate to the joint. In either case, it is not difficult to imagine how they can contribute to synovial inflammation.

Several animal models of arthritis are dependent on TLR2, TLR3, TLR4, or TLR9. For instance, rodents injected with streptococcal cell walls (TLR2 ligand) develop severe polyarticular arthritis. The initial phase of disease resolves and is then followed by a chronic T cell-dependent phase that resembles RA. The arthritogenicity of complete Freund's adjuvant in the rat adjuvant arthritis model is dependent on mycobacterial DNA that binds to TLR9 and activates an adaptive immunity. Endogenous TLR4 ligands such as heat shock proteins and fibrinogen also play a role in immune complex models such as passive K/BxN arthritis.²⁵

Mycoplasma-derived superantigens such as from *Mycoplasma arthritidis* can directly induce T cell-independent cytokine production by macrophages and can exacerbate or trigger arthritis in mice immunized with type II collagen. There is also a higher prevalence of antimycoplasma pneumoniae IgG antibodies in RA patients than matched controls. Despite this and other circumstantial evidence, most efforts to identify *Mycoplasma* and *Chlamydia* organisms or DNA in joint samples have been negative, and there is no direct evidence to support these organisms as etiologic agents.

Figure 69-3 Accumulation of bacterial peptidoglycan in rheumatoid synovium. **A** and **B**, Immunohistochemistry shows synovial cells containing peptidoglycan (red). **C**, Double staining studies show that bacterial peptidoglycan accumulates in synovial macrophages (arrow). These bacterial products can activate Toll-like receptors and stimulate cytokine production. (From Schrijver IA, Melief MJ, Tak PP, et al: *Antigen-presenting cells containing bacterial peptidoglycan in synovial tissues of rheumatoid arthritis patients coexpress costimulatory molecules and cytokines*, *Arthritis Rheum* 43:2160, 2000.)

Epstein-Barr Virus, *dnaJ* Proteins, and Molecular Mimicry

Epstein-Barr virus (EBV) is a polyclonal B lymphocyte activator that increases the production of RF, and rheumatoid macrophages and T cells have defective suppression of EBV-induced proliferation of human B cells. Rheumatoid patients have higher levels of EBV shedding in throat washings, an increased number of virus-infected B cells in the circulating blood, higher levels of antibodies to normal and citrullinated EBV antigens, and abnormal EBV-specific cytotoxic T cell responsiveness compared with controls. Defective elimination of EBV-transformed lymphocytes in RA has fueled speculation that a specific immune defect contributes to initiation of disease.

Additional intriguing data implicating EBV in RA are derived from sequence homology between the susceptibility cassette in HLA-DR proteins and the EBV glycoprotein gp110. Like DRB*0401, gp110 contains the QKRAA motif and patients with serologic evidence of a previous EBV infection have antibodies against this epitope. Hence T cell recognition of EBV epitopes in some patients with the SE

might cause an immune response directed at innocent bystander cells through “molecular mimicry.” This hypothesis could potentially account for disease perpetuation in the absence of active infection in patients with a specific MHC genotype. However, the data are circumstantial and gp110 is only one of many xenoproteins such as the *Escherichia coli* heat shock protein *dnaJ* that contain QKRAA. RA T cells, especially synovial fluid T cells, have increased proliferative responses to gp110, perhaps supporting the molecular-mimicry link between a variety of QKRAA-containing proteins and arthritis.

Parvovirus

Antecedent infection with parvovirus B19 has been implicated in some patients with RA based on serologic evidence including the nonstructural protein NS1. However, only about 5% of patients have evidence of recently acquired parvovirus B19 infection at the time of disease onset. Of interest, 75% of RA synovium samples contain B19 DNA compared with about 20% of non-RA controls. Immunohistochemical evidence of the B19 protein VP-1 was detected in patients with RA but not other forms of arthritis. However, evidence of the B19 genome in RA joint samples was not found in other studies.

The mechanisms of B19-induced synovitis, when it does occur, could be related to alterations in the function of FLS.²⁶ In a cell-culture model of synoviocyte invasion into cartilage, infection with the parvovirus significantly increased the migration of cells into the matrix. Mice that are transgenic for the B19 protein NS1 were more susceptible to collagen-induced arthritis and developed high titers of anti-type II collagen antibodies. These data suggest that the B19 genome might not cause arthritis but can enhance an arthritogenic response to other environmental stimuli.

Other Viruses

Because rubella virus and the rubella vaccine can cause arthritis in humans, the virus has attracted some attention as a possible triggering agent. Live rubella virus can be isolated from synovial fluid of some patients with chronic inflammatory oligoarthritis or polyarthritis without clinical evidence of rubella. However, most rubella patients do not have the classic polyarticular involvement and display an oligoarthritis involving large joints. As with B19 infection, it is possible that a small subset of patients with chronic polyarthritis that are called RA actually have direct infection with wild-type or attenuated rubella virus.

Studies of synovial tissue in a variety of inflammatory and noninflammatory arthropathies have also demonstrated DNA of other viruses such as cytomegalovirus and herpes simplex, but not adenovirus or varicella-zoster. As with bacterial DNA, parvovirus, and EBV, the localization of viral DNA to the inflamed joint might be related to the migration of inflammatory cells containing the viral genome or other nonspecific mechanisms rather than an active infection. Although the hypothesis that one or more of these viral infections might serve as a triggering agent in the genetically susceptible host is both appealing and intellectually satisfying, the pathogenic role of these agents is unlikely.

Retroviral infections have been suggested as a cause of RA. Extensive searches for potential agents have not been fruitful. Endogenous retroviruses are abundant in inflamed and normal synovium, and certain transcripts are expressed in RA cells. In one study, higher levels of HERV-K10 gag protein from a common endogenous retrovirus were detected more often in RA compared with OA and normal peripheral blood mononuclear cells. Some indirect studies are suggestive of retroviral infection such as the demonstration of zinc-finger transcription factors in cultured synoviocytes that can increase signaling through enzymes like p38 mitogen-activated protein (MAP) kinase. In addition, the pX domain of one human retrovirus, human T lymphotropic virus-1 (HTLV-1), causes synovitis in transgenic mice, and synoviocytes from patients infected with HTLV-1 have increased cytokine production. Other studies failed to demonstrate increased expression of human retrovirus-5 proviral DNA in rheumatoid synovium. There is still no direct evidence that retroviruses cause RA, but some viral products could activate TLR3 or TLR7 to enhance cytokine and chemokine production.

Autoimmunity

KEY POINTS

Evidence of autoimmunity can be present in RA many years before the onset of clinical arthritis.

Autoantibodies such as RFs and anticitrullinated protein antibodies are commonly associated with RA.

Autoantibodies in RA can either recognize joint antigens such as type II collagen, or systemic antigens such as glucose phosphate isomerase.

These autoantibodies can potentially contribute to synovial inflammation through several mechanisms including local activation of complement.

The idea that aberrant immune responses are directed toward self-antigens in RA was recognized with the discovery of RF in the blood of patients with the disease. Initially described by Waaler and later by Rose, it was not until the mid-1950s that Kunkel and colleagues firmly established that RF is an autoantibody. Although our understanding of autoantigens has changed over the years and the relative contributions of cellular and humoral immunity have been debated, emphasis on the role of autoantibodies in RA has enjoyed a resurgence over the past few years. Clinical improvement can be associated with decreases in levels of RFs or ACPAs, although the changes tend to be modest and are inconsistent.

Rheumatoid Factor

The identification and characterization of RF as an autoantibody that binds to the Fc portion of IgG was the first direct evidence that autoimmunity might play a role in RA. For many years, immune complexes comprising RF and other immunoglobulins were thought to play a primary role in the pathogenesis of synovitis (see Chapter 56). Even today, the

presence of RF and its resultant pathogenic consequences are still considered cardinal features of RA. Longitudinal studies show that production of RF and other autoantibodies can precede the onset of RA by many years (Figure 69-4).²⁷ Although some patients are initially “seronegative” for RA and subsequently convert to “seropositive,” this is rather unusual and seroconversion typically occurs during the first year of disease activity.

The role of RF and other autoantibodies in the pathogenesis of RA has been suggested by circumstantial evidence. For instance, patients with a positive test result for RF in blood have more severe clinical disease and complications than seronegative patients including increased cardiovascular complications.²⁸ RF can also fix and activate complement by the classic pathway, and there is clear evidence of local complement production and consumption in the rheumatoid joint. Large quantities of IgG RF are produced by rheumatoid synovial tissue and form complexes through self-association. RF-containing immune complexes are readily detected in RA synovial tissue, as well as the surface layers of cartilage. The latter is especially relevant because immobilized complexes can facilitate complement fixation with resultant release of chemotactic peptides. In experiments performed in patients with RA, a marked inflammatory response was elicited when RF from one patient was injected into a joint, but not when normal IgG was given.²⁹ B cell–targeted therapies such as rituximab can deplete peripheral B lymphocytes and modestly decrease titers of RF. This does not correlate precisely with clinical responses, and synovial RF production is not significantly changed by B cell depletion. Nevertheless, RF levels often decrease in responders and increase again coincident with clinical relapses.

Three-quarters of patients with RA are seropositive using standard tests for RF, although the percentage can be as high as 90% when assayed for IgM RF with enzyme-linked immunosorbent assays. First-degree relatives of seropositive patients with RA are frequently seropositive, suggesting a

Figure 69-4 Autoantibody production in rheumatoid arthritis. Rheumatoid factors and anticitrullinated protein antibodies (ACPAs) are detected in the blood long before the onset of clinical arthritis in many patients. (From Nielen MM, van Schaardenburg D, Reesink HW, et al: Specific autoantibodies precede the symptoms of rheumatoid arthritis: a study of serial measurements in blood donors, *Arthritis Rheum* 50:380, 2004.)

genetic contribution. Although IgG and IgM RFs are the most abundant in RA, IgE RF has also been demonstrated, especially in patients with extra-articular manifestations. IgE RF can potentially complex with aggregated IgG in synovial tissue, and the subsequent complexes then could degranulate synovial mast cells through activation of Fc receptors in the synovium. IgA RFs are also produced in RA including patients who are seronegative as determined by standard clinical tests that primarily detect IgM RF.

The RFs produced in RA differ from those produced by healthy individuals or from patients with paraproteins. The avidity of RF for the Fc portion of IgG is much greater in RA than in Waldenström's macroglobulinemia or in cryoglobulins. Many RFs expressed by abnormal B cells (such as Waldenström's macroglobulinemia) and by normal B cells in human tonsils are derived from the germline. In contrast, RFs in RA are derived through rearrangements and somatic mutations of the germline genes. RF production can be quite high in rheumatoid synovium; IgM RF represents about 7% of the total IgM and 3% of the total IgG produced by synovial cell cultures.

RFs in RA primarily use the variable heavy 3 (VH3) gene and a variety of variable light (VL) genes, whereas natural antibodies with RF activity use VH1 or VH4 and the VK3 genes.³⁰ The kappa light chain repertoire expressed in RF-producing cells isolated from one RA patient was enriched for two specific VK genes but contained many somatic mutations and non-germline-encoded nucleotides.³¹ Therefore the selection and production of these specific RFs were likely due to antigenic drive rather than derived directly from the germline. Additional RFs have been identified with characteristics similar to an antigen-driven response, although some examples of germline RFs have also been isolated from RA synovium. A crystal

structure of one IgM RF bound to IgG showed a key contact residue of the RF with the Fc portion of IgG containing a somatic mutation, supporting the notion that the mutations are related to affinity maturation.

Anticitrullinated Protein Antibodies (ACPAs). One of the most striking recent observations related to autoantibodies is the observation that immunoglobulins that bind to citrullinated proteins are produced by patients with RA and have significant prognostic implications. The discovery originated with reports in the 1970s that antibodies directed against keratin were detected in rheumatoid serum and that the primary target antigen was filament-aggregating protein, filaggrin. These antibodies actually bind to epitopes on filaggrin that contain citrulline, which is derived from post-translational modification of arginine by PADI. Humans have four isoforms of PADI. PADI2 and PADI4 are especially abundant in synovium,³² and certain SNPs are associated with RA in Asian populations. The function of PADIs in normal immune responses is not certain; citrullination of some chemokines can decrease activity, and modification of histones can regulate gene expression in stressed cells.

Induction of *PADI* expression and citrullination of peptides are not specific to RA and can occur in many inflammatory settings.³³ Not only are other inflammatory arthropathies marked by citrullinated proteins, but other organs such as the lungs in smokers have significant *PADI* activity. The presence of CPs in the lungs of smokers could provide the systemic antigen exposure that can contribute to anti-CP antibody production and begin the long road to developing RA. CPs are present in most animal models of arthritis. Immunohistochemistry demonstrates citrullinated proteins in RA synovial tissue infiltrating cells (Figure 69-5), as well as in extracellular deposits that often colocalize with various isoforms of *PADI*, especially *PADI2* and

Figure 69-5 A to D, Citrullinated proteins in inflamed synovium. Both rheumatoid arthritis and nonrheumatoid synovium contain citrullinated proteins, detected with an anticyclic citrullinated protein (anti-CCP) antibody (red-brown in synovium). Control is an irrelevant antibody. Although citrullinated proteins are not specific, the production of anticitrullinated protein antibodies is more specific to rheumatoid arthritis. (From Vossenaar ER, Smeets TJ, Kraan MC, et al: The presence of citrullinated proteins is not specific for rheumatoid synovial tissue, *Arthritis Rheum* 50:3485, 2004.)

PADI4. Moreover, ACPAs are produced by the rheumatoid synovium, especially tissues with lymphoid aggregates.

The specific proteins that are modified vary widely but include many normal constituents like fibrinogen, vimentin, and fibronectin, as well as xenoproteins like EBV-derived peptides.³⁴ The pattern of protein citrullination or the specificity of antibodies to particular proteins does not, thus far, have predictive value for developing RA or the severity of disease. One interesting subset involves antibodies that recognize mutant citrullinated vimentin (MCV). These antigens have two modifications that render them more immunogenic: First, there are amino acid changes in the primary sequence such as glycine to arginine. Second, either the new amino acid or another arginine on the protein is citrullinated.³⁵ The mechanism of amino acid changes has not been defined but could be due to oxidative stress that causes mutations in the genes encoding the protein. These anti-MCV antibodies might be more specific for RA in established disease and also might be more predictive for radiographic progression than standard ACPA tests.³⁶

ACPs are present in the serum of 80% to 90% of RA patients. In some studies, they are also more specific for RA than RF, with specificity approaching 90%. Perhaps most interesting, ACPA, like RF, can appear long before the onset of clinical arthritis and could be a marker for immune hyper-reactivity and subclinical inflammation leading to protein citrullination in a variety of tissues. The more peptides recognized by the repertoire of ACPAs, such as to vimentin, enolase, or various fragments of fibronectin, the greater the likelihood that an individual with arthralgias will develop RA.³⁷ Of interest, elevated serum cytokines also predicts development of arthritis that meets criteria for RA.³⁸ A genetic contribution was confirmed in the Native American population, where ACPAs are present in nearly 20% of unaffected first-degree relatives and more than 10% of more distant relatives.³⁹ ACPAs are also produced by synovial tissue B cells and can be detected in synovial fluid. However, the fact that ACPAs, like RFs, can be detected years before the onset of arthritis and can be found in some normal relatives of RA patients suggests that the autoantibodies alone cannot account for the etiology of the disease.

ACPs are predictors of more aggressive disease marked by bone and cartilage destruction. In fact, some data suggest that the HLA-DR associations in RA are actually due to an association between the susceptibility epitope and ACPA production. This association extends to accelerated atherosclerosis in RA, where anti-CP positivity is an independent risk factor for ischemic heart disease. In patients with early undifferentiated inflammatory arthritis, ACPAs are also predictive for individuals who will progress to RA.⁴⁰

Despite these caveats, ACPAs do have pathogenic potential. For instance, ACPAs can activate the classical and the alternative complement pathways.⁴¹ In addition, IgE ACPAs from patients with RA can sensitize basophils and mast cells to degranulate. This could enhance increased vascular permeability and influx of inflammatory cells into the synovium.⁴² The antibodies have minimal effect when directly injected into mice, and they enhance the arthritogenic potential of anti-type II collagen antibodies in the collagen-induced arthritis model.⁴³ Mice immunized with

citrullinated fibronectin, but not native fibronectin, can develop inflammatory arthritis.⁴⁴ Hence the autoreactivity and autoantibodies are not simply a marker of disease but can participate in the disease process. Citrullination can also increase T cell responses to arthritogenic antigens. For instance, citrullination of albumin leads to the formation of antibodies that also cross-react with the unmodified protein. The citrullinated type II collagen is more immunogenic than the native protein, most likely due to increased affinity in the binding groove of HLA-DR proteins that contain the SE.⁴⁵

Autoimmunity to Cartilage-Specific Antigens

Because synovial tissue inflammation is a hallmark of RA, it is only natural to assume that certain joint-specific antigens might play an etiologic or pathogenic role. The number of potential antigens is extensive, and there is no convincing evidence to date that one specific “rheumatoid” antigen exists. In contrast, the emerging picture of autoimmunity in RA tends to implicate patterns of self-directed responses, rather than a single epitope that encompasses all patients at all times during the disease. It is quite possible that articular autoimmunity could vary with the stage of disease, the clinical manifestations, and treatment.

Type II Collagen. The discoveries that immunization with type II collagen can cause arthritis in rats and mice and that the disease can be passively transferred by IgG fractions containing anticollagen antibodies or by transfer of lymphocytes from affected animals have spawned extensive experiments that illustrate the antigenicity of collagen, the arthrotropic nature of the disease produced, and the dependence on class II MHC genes. T cells are required for initiation of collagen-induced arthritis, and a major immunogenic and arthritogenic epitope on type II collagen resides in a restricted area of the type II collagen chains.

However, type II collagen antibody generation is probably not the initiating event in RA but can amplify the inflammatory response (Table 69-4). Sera from patients with RA contain antibody titers to denatured bovine type II collagen that are significantly higher than those found in control sera⁴⁶; however, there is no difference in antibody titers to native collagen, indicating that the denatured form generated after the breakdown of connective tissue might serve as the immunogen. Anticollagen antibodies purified from the sera of patients with RA can activate complement,

generating C5a when they bind to cartilage. In addition, isolated synovial tissue B lymphocytes actively secrete anti-type II collagen antibodies in almost all patients with seropositive RA, whereas articular cells from non-RA patients do not. Synovial fluid T cells also recognize and respond to type II collagen, and 3% to 5% of RA synovial fluid-derived T cell clones are autoreactive to the protein. Of interest, T cell responses to type II collagen, especially a dominant epitope at amino acid 263-270, are much greater if the epitope is glycosylated or if the protein is citrullinated.⁴⁷

gp39 and Other Cartilage-Specific Antigens. Several other cartilage components besides type II collagen have been implicated as potential autoantigens in RA. Among the most provocative is cartilage glycoprotein gp39. Several gp39 peptides can bind to the HLA-DR*0401 molecule and stimulate proliferation of T cells from patients with RA. BALB/c mice, which are often resistant to experimental arthritis, develop polyarticular inflammatory arthritis after immunization with gp39 and complete Freund's adjuvant. Although anti-gp39 antibodies are only detected in a small percentage of patients, it appears to be relatively specific for RA.⁴⁸ Other examples of potential cartilage autoantigens include proteoglycans, aggrecan, cartilage-link protein, and other types of collagen. Proteomic analysis of RA serum using peptide arrays to detect multiple autoantibodies also identifies anti-gp39 antibodies in patients with early RA, which may be associated with less aggressive disease.

Autoimmunity to Nonarticular Antigens

Autoimmune responses in RA can also involve antigens that are broadly expressed beyond the joint.⁴⁹ These antigen-antibody systems comprise a pattern of autoimmune responses that can potentially lead to synovial inflammation.

Glucose-6-Phosphoisomerase

Spontaneous inflammatory arthritis develops in K/BxN mice due to antigen-specific immunity against a seemingly irrelevant nonarticular antigen.⁵⁰ Autoantibodies to the ubiquitous enzyme, glucose-6-phosphate isomerase (GPI) cause the disease, and transient synovitis also develops in normal mice injected with the serum of the affected K/BxN mice. This passive arthritis model serves as a unique tool to study antibody-dependent arthritis and requires the alternate complement pathway, Fc receptors (especially FcγIII), and mast cells, but not T or B cells. IL-1 is more important than TNF in this model, and the IL-1 knockout mice are almost completely protected from disease. Notably, this effect can be overcome by administration of a TLR ligand like lipopolysaccharide, which shares a downstream signaling pathway with IL-1. Other cytokines, such as IL-6, and signaling pathways, such as p38 MAP kinase and upstream kinases such as MKK3, are also required for full expression of the disease.

Immunohistochemical studies show that the target protein, GPI, adheres to the surface of cartilage, which permits local antibody binding and complement fixation. Initiation of synovial inflammation requires mast cells that increase vascular permeability and provide access to the synovium and cartilage.⁵¹ The initial phase involving mast

cell and vascular permeability is augmented by antibody-mediated complement fixation when serum proteins have access to GPI-decorated cartilage.

Although the model appears on first blush to be due to a ubiquitous antigen, articular homing and display of the GPI suggest that it behaves like other arthritis models with "joint-specific" antigens. Although initial data suggested some specificity for RA, anti-GPI antibodies are detected in a relatively small percentage of RA patients and are not specific for the disease. Nevertheless, it might, along with several other antibody systems, contribute to local complement fixation and inflammation.

Heterogeneous Nuclear Ribonucleoprotein-A2 and Heavy-Chain Binding Protein. Several other autoantigens that are expressed in synovium have been characterized in RA, although they are also produced in many other locations. For instance, antibodies directed against the heterogeneous nuclear ribonucleoprotein-A2 (hnRNP-A2), sometimes called RA33, occur in about one-third of RA patients, as well as patients with other systemic autoimmune diseases. However, there may be some specificity for RA when compared with OA and seronegative spondyloarthropathies. Anti-RA33 antibodies are also produced in the TNF transgenic mouse model of rheumatoid arthritis, suggesting that proinflammatory cytokines can independently lead to a breakdown of tolerance for this particular protein.⁵² Of interest, RA33-positive patients with early RA tended to have less destructive disease.⁵³ Although not especially sensitive or specific for RA when used in isolation, an algorithm involving anti-RNP-A2, RF, and anti-CP can be used to predict patients with early synovitis who will progress to erosive RA.⁵⁴

Autoantibodies that bind to stress-protein immunoglobulin heavy-chain binding protein (BiP) have also been observed. About 60% of RA patients have anti-BiP antibodies, and the specificity is reportedly more than 90%. In addition to humoral responses, RA T cells can proliferate in response to this protein. Immunization of mice with BiP does not cause arthritis, but it can cross-tolerize mice and prevent collagen-induced arthritis if administered before immunization with type II collagen. BiP is normally expressed in many tissues but is markedly increased in RA synovium.

Heat Shock Proteins. The heat shock proteins (HSPs) are a family of mainly medium-sized (60 to 90 kD) proteins produced by cells of all species in response to stress. Another smaller HSP (HSP27) can serve as substrates for enzymes such as p38 MAP kinase that regulate stress responses. Immunity against HSPs contributes directly to synovitis and joint destruction in the adjuvant arthritis model in rats in which T lymphocytes recognize an epitope of mycobacterial HSP65 (amino acids 180 through 188). Some of these cells also recognize cartilage proteoglycan epitopes, perhaps explaining the targeting of joints.

Some patients with RA have elevated levels of antibodies to mycobacterial HSPs, especially in synovial fluid. The majority of T cell clones isolated from RA synovial fluid with specificity to mycobacterial components express the γδ-T cell receptor and do not display CD4 or CD8 surface antigens. Freshly isolated synovial fluid T cells from patients with RA briskly proliferate in response to recombinant 65-kD HSP. However, proliferation to other recall antigens

such as tetanus toxoid is not increased. Synovial fluid mononuclear cells activated by 60-kD mycobacterial HSP inhibit proteoglycan production by human cartilage explants. Human HSPs including the HSP60 are expressed in the synovium, although the amount expressed per cell appears to be similar in OA, RA, and normal tissue.

SYNOVIAL PATHOLOGY AND BIOLOGY

KEY POINTS

The synovium in RA is marked by intimal lining hyperplasia and sublining infiltration with mononuclear cells, especially CD4⁺ T cells, macrophages, and B cells.

Intimal lining FLS display unusually aggressive features.

Macrophages in the intimal lining are highly activated and produce many cytokines.

Lymphocytes can either diffusely infiltrate the sublining or form lymphoid aggregates with germinal centers.

Sublining CD4⁺ T cells mainly display the memory cell phenotype.

Synovial B cells and plasma cells in RA exhibit evidence of antigen-driven maturation and antibody production.

Dendritic cells can potentially present antigens to T cells in synovial germinal centers.

Mast cells produce small molecule mediators of inflammation.

Neutrophils are rarely present in RA synovium but can be abundant in synovial effusions.

The primary inflammatory site in RA is the synovium. Infiltration of synovial tissue with mononuclear cells, especially T cells and macrophages, and synovial intimal lining hyperplasia are hallmarks of the disease (Figure 69-6). In this section, the various cell lineages and histologic patterns of rheumatoid synovium are discussed.

Synovial Intimal Lining Cells: Type A and Type B Synoviocytes

The synovial intimal lining is a loosely organized collection of cells that form an interface between the synovium and

the synovial fluid space. The intimal lining cells lack tight junctions and a definite basement membrane. The increase in cell number in RA can be quite substantial. In the normal joint, the lining is only one to two cell layers deep, whereas in RA it is often 4 to 10 cells deep. Two major cell types are found in the lining: a macrophage-like cell known as a type A synoviocyte and a fibroblast-like cell called a type B synoviocyte. The former are derived from the bone marrow and express macrophage surface markers such as CD68, Fc receptors, and CD14, as well as abundant HLA-DR, whereas the latter express little if any class II MHC antigens, are devoid of macrophage markers, and have a scant endoplasmic reticulum. The type B cells, also called FLS, express certain proteins that are unusual for mesenchymal cells including vascular cell adhesion molecule-1 (VCAM-1), CD55 (decay activating factor), cadherin-11, junctional adhesion molecule C (JAM-C), and the proteoglycan-synthesis enzyme, uridine diphosphoglucose dehydrogenase (UDPGD). The relative numbers of type A and B cells are usually similar in normal synovium. There is an absolute increase in both cell types in RA, although the percentage increase in macrophage-like cells is often greater. In addition, the type A synoviocytes tend to accumulate in the more superficial regions of the intimal lining.

Intimal lining synovial macrophages and sublining macrophages are terminally differentiated cells that presumably do not divide in the joint, and the accumulation of cells in RA is likely from the ingress of new bone marrow-derived precursors. Mesenchymally derived type B synoviocytes can divide locally in response to the proliferative factors generated by the activated immune response. Platelet-derived growth factor (PDGF), transforming growth factor-beta (TGF- β), TNF, and IL-1 produced by many different cells combine with products of arachidonic acid metabolism to induce proliferation of these cells. In addition, pluripotent mesenchymal stem cells that arise in the bone marrow and circulate through the blood can migrate into the synovium and differentiate into type B synoviocytes.⁵⁵ Retention of macrophages in the intimal lining is probably due to expression of adhesion molecules like VCAM-1 and JAM-C on FLS.

Although local proliferation of cells in the intimal lining likely occurs, rheumatoid synovium rarely shows mitotic figures, and thymidine uptake occurs in only a small percentage of synovial cells. Using a monoclonal antibody that recognizes dividing cells, an even lower rate of cell division

Figure 69-6 Histopathologic appearance of rheumatoid arthritis synovium. Intimal lining hyperplasia, angiogenesis, and a prominent mononuclear cell infiltrate are present. Panels show standard histology (left panel), as well as immunostaining for macrophages (brown in the intimal lining, middle panel) and a perivascular T cell aggregate (right panel). (Courtesy Dr. Paul-Peter Tak.)

($\approx 0.05\%$) is apparent.⁵⁶ A somewhat higher percentage of cells that express the cell cycle-specific antigen proliferating cell nuclear antigen (PCNA) is present in RA lining compared with OA. This correlates with the lining cell expression of the proto-oncogene *c-myc*, a gene that is intimately linked with fibroblast proliferation.

The architecture of the synovial intimal lining is distinct from other lining layers in the body. In contrast to serosal surfaces, the intimal lining does not include epithelial cells, it lacks a basement membrane, and has no tight junctions. Rather than serving as a discrete barrier, it is a loose association of cells that is discontinuous in some locations. Cadherin-11, from a class of adhesion proteins that are ubiquitous in various tissues, serves as the major mediator of homotypic aggregation by FLS.⁵⁷ Immunohistochemistry shows abundant expression of this protein in the intimal lining. Its importance in the synovial architecture was confirmed in cadherin-11 knockout mice, in which the intimal lining was virtually nonexistent. Finally, cadherin-11 mediates self-aggregation of FLS in vitro. When the cells are cultured in “micromasses” made of laminin, they migrate to the surface of the particles (Figure 69-7). Macrophages cocultured in the micromasses leads to recruitment of these cells to the surface as well, thereby recapitulating a lining layer with macrophage-like and fibroblast-like cells.⁵⁸ Blocking cadherin-11 with antibodies suppresses arthritis in the passive K/BxN model. These data suggest that FLS not only

organize the intimal lining formation, but also, like T cells, B cells, and macrophages, play a critical role in the pathogenesis of inflammatory arthritis.

Two major populations of adherent cells can be readily identified when rheumatoid synovium is enzymatically dispersed and cultured in vitro. One type of cell is macrophage-like, which expresses HLA-DR antigens, Fc receptors, and monocyte lineage-differentiation antigens and is capable of phagocytosis. The macrophages, which comprise about 20% of the total cell number in the rheumatoid joint, can be derived either from the intimal lining or the sublining region. These cells are highly activated in the synovium and produce large amounts of inflammatory mediators including cytokines and arachidonic acid metabolites.

A second type is defined by the presence of antigens expressed primarily on fibroblasts and by the absence of phagocytic capability, DR antigens, or antigens of the monocytic lineage. When the enzymatically dispersed cells are cultured for several passages, this latter cell type survives and proliferates, resulting in a relatively homogeneous population of fibroblast-like cells.

Fibroblast-like cells grow slowly, with a doubling time of 5 to 7 days, and can be passaged for several months in vitro. Their doubling rate is rapid at first, perhaps due to the presence of cytokines produced by contaminating macrophages in the culture or a carryover effect from the synovial milieu. Over time, proliferation slows, and after 12 to 15 passages,

Figure 69-7 Fibroblast-like synoviocytes are programmed to form the synovial intimal lining. Human and mouse fibroblast-like synoviocytes (FLS) spontaneously form lining structures when embedded in a three-dimensional matrix composed of the matrix protein laminin. The cells migrate to the surface of the structure over 3 weeks and resemble an intact synovial lining. The figure shows parallel experiments using human (A) and mouse (C) fibroblast-like synoviocytes. Of interest, dermal fibroblasts from human (B) or mouse (D) skin do not migrate to the surface, indicating that the synoviocytes are preprogrammed for this function and that it is not a property of all fibroblasts. (From Kiener HP, Watts GF, Cui Y, et al: Synovial fibroblasts self-direct multicellular lining architecture and synthetic function in three-dimensional organ culture, *Arthritis Rheum* 62:742, 2010.)

the cells gradually become senescent and ultimately cease to grow. Although it has not been proven that these cells originate solely from the synovial intimal lining, the fact that a significant percentage of cells express VCAM-1 and CD55 suggests that at least some are derived from this region. Synovial fibroblasts from RA have some characteristics reminiscent of tumors or transformed cells (see following).

Experiments examining synovial tissue and FLS gene expression profiles suggest that specific patterns correlate with synovial histopathology.⁵⁹ FLS from highly inflamed synovium exhibited a TGF- β gene signature that has also been described in cells with features of both smooth muscle cells and fibroblasts that are found in many mucosal surfaces known as *myofibroblasts*. FLS appear to be involved in wound healing. A second pattern observed in cells derived from relatively noninflammatory RA tissue had increased expression of insulin-like growth factor-regulated genes. Whether the pathogenic processes in the synovium imprint the synoviocytes or vice versa is unknown. Attempts to distinguish RA and OA FLS expression profiles from each other have offered mixed results.

Aggressive Features of RA Fibroblast-like Synoviocytes

Tumor-like Properties. Rheumatoid FLS demonstrate some aggressive properties compared with cells obtained from other synovia or tissues. For instance, adherence to plastic or extracellular matrix is generally required for normal fibroblasts to proliferate and survive in culture. Although FLS typically grow and thrive under conditions that permit adherence, RA synoviocytes can also proliferate in an anchorage-independent manner.⁶⁰ In addition, cultured RA synoviocytes can exhibit defective contact inhibition and express a variety of transcription factors, such as c-Myc, that are typically abundant in tumor cells. Poorly regulated cell growth likely occurs in vivo as well, and studies examining X-linked genes demonstrate oligoclonality in the synoviocyte population from RA, but not OA, synovium.⁶¹ This is especially true of cells derived from the invading pannus, which is the most aggressive region of the synovium. Increased telomerase activity, another feature of transformed tissue, is also present in RA synovium and can be observed in FGF-stimulated RA synoviocytes. Epigenetic analysis suggests overexpression of certain microRNAs associated with increased cytokine production.

Matrix Invasion. The most compelling evidence suggesting that RA synoviocytes are permanently altered is derived from studies in a severe combined immunodeficiency (SCID) mouse model where synoviocytes and cartilage are coimplanted. The rheumatoid cells adhere to and invade into the cartilage matrix, whereas osteoarthritis and skin fibroblasts do not⁶² (Figure 69-8). Because these synoviocytes are devoid of T cells and macrophages, there is no contribution from an immune response to murine antigens. The invading cells express VCAM-1, which could potentially facilitate adhesion to cartilage or chondrocytes, as well as proteases that digest the cartilage matrix. More recent studies in which explants are introduced into two locations in the SCID mice show that the rheumatoid FLS can migrate from one site to another, presumably via lymphatics and the bloodstream.⁶³ This raises the intriguing possibility that imprinted, aggressive cells can “metastasize”

Figure 69-8 Invasion of rheumatoid arthritis (RA) synoviocytes into cartilage explants in severe combined immunodeficiency syndrome (SCID) mice. RA fibroblast-like synoviocytes were coimplanted with normal human cartilage into the renal capsule of SCID mice. Note that the synoviocytes attached to the cartilage and invaded into the matrix. Several chondrocytes in lacunae are also present. (Courtesy Dr. S. Gay.)

from joint to joint and contribute to the polyarticular nature of RA.

Blocking IL-1 function in the SCID model with interleukin-1 receptor antagonist (IL-1Ra), a natural antagonist to IL-1, has no effect on synoviocyte invasion but decreases perichondrocyte matrix loss. In contrast, IL-10 or blocking type I metalloproteinase, Ras, or c-Myc expression decreases invasion. Surprisingly, overexpression of soluble TNF receptors has little effect in this model. These studies suggest that excessive production of IL-1 and underexpression of IL-10 contribute to the invasive properties of RA synoviocytes. In another study, transfecting normal synoviocytes with the human papillomavirus gene encoding E6 induced the rheumatoid phenotype. The E6 protein degrades endogenous p53 tumor suppressor protein in synoviocytes. Therefore deficient p53 function can mimic the aggressive phenotype of RA FLS. Overall, these studies paint an interesting picture of RA FLS serving as key effector cells that display unique aggressive properties in inflammatory synovitis.

Synovial T Lymphocytes

Immunohistologic Patterns

In chronic RA, the synovium contains a collection of T lymphocytes that can lead to an organizational structure that resembles a lymph node. The distribution of lymphocytes in the tissue varies from discrete lymphoid aggregates to diffuse sheets of mononuclear cells, with the most prominent location for T cells being the perivascular region. These collections consist of small, CD4⁺ memory T cells (CD45RO⁺) with scant cytoplasm. Scattered few CD8⁺ T cells accumulate in the aggregates, and formation of ectopic germinal centers in RA synovial tissue may depend on them. Peripheral to these foci is a transitional zone with a heterogeneous mixture of cells including lymphocytes, occasional undifferentiated blast cells, plasma cells, and macrophages (see Figure 69-6). Synovial lymphoid aggregates occur in about 15% to 20% of patients; although

originally considered specific for RA, it is now clear that they are equally prevalent in psoriatic arthritis and are even seen in some individuals with osteoarthritis.⁶⁴ The presence of aggregates correlated with higher production of ACPAs and RF in synovium, but not with clinical disease activity.

Considerable heterogeneity exists in the histologic patterns from patient to patient and within a single joint. Synovial biopsy studies suggest that at least six sites must be evaluated to decrease the risk of sampling error to 10% to 20% or less. In situations where the synovial tissue of more than one joint from an individual patient is available, the same general histopathologic patterns are usually apparent in tissue from separate sites.

Regulation of T Cell Aggregate Formation. T cells often constitute 30% to 50% of cells in RA synovia, and most are CD4⁺. About 5% of cells are B lymphocytes or plasma cells, although in some tissues the percentage can be considerably higher. The B cells are located primarily within reactive lymphoid centers, whereas plasma cells and macrophages are often found outside these centers. This arrangement is consistent with T cell–dependent B lymphocyte activation. Plasma cells, the main immunoglobulin producers, migrate away from the germinal centers after differentiation. CD4 cells in RA synovium are in intimate contact with B lymphocytes, macrophages, and dendritic cells.

Aggregate formation is complex and involves numerous signals to orchestrate the organization of individual cell lineages. In some cases, follicular dendritic cells are present and are involved in forming true germinal centers (see later). The presence or absence of aggregates and germinal centers is a dynamic process. In one study evaluating synovial biopsies, the presence of lymphoid neogenesis was not restricted to patients with autoantibodies. Even though the cytokine and chemokine profile supports the formation of these structures, progression to fully differentiated follicles was uncommon.⁶⁵

Chemokines play a key role in the organization of tissues into lymphoid structures such as aggregates and germinal centers. CXCL13 and CCL21 appear to be especially important, and their expression in rheumatoid synovium correlates with the presence of this microarchitecture.⁶⁶ The former, in particular, is produced by synovial follicular dendritic cells. Similarly, plasma cells expressing the chemokine receptor CXCR3 are present in the rheumatoid synovium. The CXCR3 ligand, Mig/CXCL9, is highly expressed by intimal lining synoviocytes and sublining cells and recruits these cells to the T cell aggregates.⁶⁷

The architecture of lymphoid structures in rheumatoid synovium is also regulated by members of the TNF superfamily. Lymphotoxin- α and lymphotoxin- β (LT α and LT β , respectively), as well as lymphotoxin-related inducible ligand that competes for glycoprotein D binding to herpesvirus entry mediator on T cells (LIGHT) form trimeric molecules in various combinations that can bind to distinct cell surfaces. These three cytokines regulate the function and organization of lymphoid tissues. Deletion of either LT α or LT β seriously impairs lymphoid development, whereas lymph nodes develop normally in LIGHT-deficient mice. In the SCID mouse model using RA tissue explants, depletion

of CD8⁺ T cells led to loss of follicular dendritic cells, depletion of LT α 1 β 2, and disintegration of the lymphoid follicles.⁶⁸

Although LT α is difficult to detect in RA, LT β and LIGHT are present.⁶⁹ In addition to regulating lymphoid aggregate and germinal center formation, LT can also directly stimulate FLS to produce chemokines such as CCL2 and CCL5 that attract T cells into the joint. LIGHT also enhances osteoclast differentiation and induces expression of MMP-9, TNF, IL-6, and IL-8 by macrophages. LT β and LIGHT blockade using soluble receptors decreases the severity of collagen-induced arthritis.⁷⁰ However, the inhibitor was not effective in the passive arthritis model in which the pathogenic antibodies were directly administered to mice. Hence the LIGHT axis has a more important role in the early phases of disease when adaptive immunity to joint antigens is developing.

Synovial T Cell Phenotype

Co-stimulatory Molecules. RA synovial T lymphocytes display an activated surface phenotype, with high expression of HLA-DR, CD69, and CD27. The co-stimulatory molecule CD28 is highly expressed by synovial T cells in RA. Its ligands, CD80 and CD86, are also displayed on antigen-presenting cells in the joint, thereby providing an excellent environment for T cell activation. The importance of the CD80/86-CD28 interaction is supported by the observation that abatacept blocks CD80/86 and is effective in RA. Oligoclonal expansion of an unusual T cell population that is CD4⁺CD28⁻ is present in RA, especially patients with extra-articular disease.⁷¹ The cells can be cytotoxic and can respond to autoantigens. Other co-stimulatory molecule pairs such as CD40L on T cells and CD40 on antigen-presenting cells are also expressed in RA synovium.

Adhesion Molecules. Synovial lymphocytes also express adhesion molecules of the very late activation antigen (VLA) and lymphocyte function-associated antigen (LFA) superfamily of integrins, as well as help recruit and retain lymphocytes to the synovium. The cytokine milieu of the joint induces adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), VCAM-1, and connecting segment-1 (CS-1) fibronectin on vascular endothelium. These, in conjunction with chemokines and other chemoattractants, attract cells expressing the correct adhesion molecule counter-receptors on their surface.

Chemokine Receptors. Synovial T cells in RA express characteristic receptors to specific chemokines. The chemokine receptor CCR5 is the ligand for macrophage inhibitory proteins 1 α and 1 β and is highly expressed in the infiltrating RA T cells. This particular receptor, along with CXCR3, is preferentially found on Th1 cells, an observation that might explain accumulation of this phenotype in the rheumatoid synovium. In fact, expression of nonfunctional CCR5 alleles that protect from HIV infection might diminish the risk of RA. The chemotactic factor stromal cell–derived factor-1 (SDF-1) is also produced by synovial tissue, and its specific receptor, CXCR4, is displayed by rheumatoid synovial T cells. Other T cell phenotypes recruited to the rheumatoid synovium include Th17 cells that express CCR2 or CCR6 and produce IL-17 and CD4⁺CD25⁺ Treg cells that can suppress immune responses (see discussion of T cell subsets

later). Preferential recruitment of CCR6⁺ Th17 cells into the rheumatoid joint appears to be due to the local release of the chemokine CCL20.⁷²

T Cell Receptor Rearrangements. Numerous groups evaluated T cell receptor gene rearrangements for clues related to antigen-specific expansion. In some patients, a pattern emerged suggesting an increased number of T cells expressing V β 3, V β 14, and V β 17, especially in synovial tissue. These particular V β genes are structurally related and are unusually susceptible to activation by superantigens. Most studies have neither found evidence for the restricted clonality of T cells in RA synovial fluid, synovial tissue, and blood nor identified expansion of different V β or V α genes.

Determinants of T Cell Phenotype. The local accumulation of T cells in the joint is not necessarily related to proliferation induced by particular antigen. Instead, antigen-independent processes related to the expression of chemokines and adhesion molecules on vascular endothelium and circulating lymphocytes help determine the mononuclear cell infiltrate. Although local antigen-specific expansion can occur, it is probably responsible for a relatively small percentage of the T cell infiltrate. Cells that encounter their appropriate antigen in the correct cytokine and antigen-presenting cell environment can potentially activate other local cells through direct cell-cell contact or the elaboration of lymphokines. A high level of telomerase activity is also present in synovial lymphocytes in RA, which is a reflection of their proliferative activity and correlates with the severity of synovial inflammation.⁷³ However, some data suggest that telomerase activity is actually defective in RA T cells and contributes to early senescence of the immune system. An alternative explanation for T cell activation in RA is that antigen presentation mainly occurs in central lymphoid organs. In this scenario, dendritic cells that encounter antigens in the synovium or other sites migrate to lymphatic tissue and then present antigen to naïve T cells. Once activated, these T cells enter the circulation and can home to the joint, where they can produce cytokines and activate resident cells.

Synovial T Cell Immunoreactivity

The histopathologic appearance of RA, with exuberant infiltration of the synovium with T lymphocytes, is characteristic of tissues with chronic antigen-specific responses. However, the synovium can only respond to inflammation in a limited number of ways and many chronic immune-mediated arthropathies have similar histologic patterns. In fact, the appearance of chronic arthritides that are clearly not mediated by T cells (e.g., chronic tophaceous gout) exhibits many of the same features.

The microheterogeneity of the rheumatoid synovial tissue, with different numbers and proportions of cell lineages in each area, suggests that different antigens might be presented at various locations in the synovium. For instance, type II collagen might be presented to T cells one place, proteoglycans elsewhere, and responses to HSPs or viral antigens in yet another region. Although synovial T cells display an activated phenotype, proliferative and cytokine responses are usually less than normal peripheral blood cells

or even autologous peripheral blood T cells from the same patient. Spontaneous and stimulated cytokine production including Th1 factors such as IFN- γ and IL-2 are relatively low. Responses directed toward recall antigens are also deficient, although RA synovial T cells can proliferate briskly to certain HSPs. On the other hand, recent data implicate functional Th17 cells in the synovium, which differentiate in the presence of certain cytokines such as IL-1, IL-6, and/or IL-23 and produce cytokines in the IL-17 family (IL-17A through F).

The mechanisms of decreased responsiveness in the synovial tissue compartment have not been as extensively studied as in synovial fluid or peripheral blood, but they likely include exposure to suppressive factors (e.g., TGF- β or IL-1Ra), abnormal redox potentials that suppress T cell receptor signal transduction, or induction of anergy. Another contributor to local anergy is the relative lack of the costimulatory molecule CD80 on HLA-DR⁺ FLS because coculture of T cells with synoviocytes suppresses subsequent immune responses.

Synovial T cells in RA functionally resemble resting peripheral blood T lymphocytes that have been activated by cytokines rather than antigen.⁷⁴ Both synovial and blood T lymphocytes are able to stimulate macrophages to produce TNF in a cell contact-dependent manner. This process is dependent on nuclear factor κ B (NF κ B) and is mechanistically distinct from T cell activation via the T cell receptor, which is independent of NF κ B. Therefore the contribution of T cell to the proinflammatory cytokine milieu may be unrelated to antigen-mediated events and could result from passive activation after exposure to the cytokine environment.

Although increased immune reactivity contributes to the etiology of RA, the search for a specific rheumatoid antigen has not been fruitful. Animal models suggest that breakdown of tolerance can be due to a combination of factors early in development. For instance, mutations in the ZAP70 gene can lead to spontaneous T cell-dependent inflammatory arthritis in mice.⁷⁵ This protein is intimately involved with transducing T cell receptor signals and activating T lymphocytes. An abnormal ZAP70 gene leads to defective positive and negative selection in the thymus and allows autoreactive T cells to escape. As a result, mice produce autoantibodies (e.g., RF and anti-dsDNA) and develop a severe destructive arthritis. The disease can be transferred by thymocytes or peripheral CD4⁺ T cells into syngeneic mice with a normal ZAP70 gene.

The cytokine profile of this model is quite similar to RA, and mice with deficient TNF, IL-1, or IL-6 have reduced synovitis. Of interest, IFN- γ deficiency has no effect, whereas IL-10 deficiency exacerbates disease. These studies demonstrate that minor changes in the T cell receptor complex and signaling can alter T cell selection and induce T cell-dependent arthritis. This is especially relevant in light of the data implicating PTPN22 in RA because this gene is also involved with T cell receptor signaling. Despite the clear T cell dependence of the model, the cytokines implicated are remarkably similar to autoantibody-dependent models of RA. Therefore the cytokine profile in RA (see later) in many ways represents a final common pathway for a variety of autoimmune mechanisms.

Restoring T Cell Tolerance

Assuming that synovial T cell autoreactivity plays a key role in the pathogenesis of RA, one potential therapeutic approach is to restore tolerance. This concept has been somewhat problematic because the underlying defect has not been defined and could include abnormal thymic selection, poorly defined genetic factors that lead to immune hyper-reactivity, or inadequate regulatory T cell function. The lack of a specific antigen identified as pathogenic also increases the complexity of the problem. What is clear, however, is that current approaches do not “cure” RA because cessation of therapy usually leads to a recurrence of disease.

Aggressive treatment of early RA (within the year of clinical disease) with methotrexate and a TNF inhibitor could lead to long-lasting remissions.⁷⁶ In many cases, therapy was withdrawn after 1 year of treatment and patients did not flare for at least an additional year. The mechanism of prolonged remission despite discontinuing therapy in early disease is not defined but appears to differ from clinical experience in chronic RA. Additional individualized therapies that enhance regulatory T cell function, alter costimulation, or delete pathogenic T cells are other ways to restore homeostasis and normal immune function. Examples might include inhibitors of co-stimulatory molecules like CTLA4 or ICOS or to potentially delete subpopulations of T cells that express specific T cell receptor that bind to epitopes critical for autoreactivity. However, the latter strategy based on specific T cell V β genes over-represented in RA joints has not been successful.

Synovial B Cells

Synovial B cell and plasma cell hyper-reactivity are viewed increasingly as key participants in the perpetuation and initiation phases of RA. This notion has been fueled by the descriptions of novel spontaneous models of arthritis in mice, such as the K/BxN model, in which loss of tolerance leads to autoantibody production, activation of innate immunity, and chronic synovitis. Furthermore, B cell-directed therapies such as anti-CD20 antibody have demonstrated efficacy in RA.

Cytokine Regulation of Synovial B Cells. Although many rheumatoid synovial tissues exhibit a diffuse infiltration with mononuclear cells, a significant percentage also have discrete lymphoid follicles populated by B cells in the sublining region. Follicular dendritic cells, B cells, plasma cells, and T lymphocytes collect in these aggregates. The germinal centers are highly organized structures in which affinity maturation occurs. B cells are present in the aggregates and express the maturation marker CD20, as well as proliferation antigens such as Ki67. The formation of these structures is dependent on several soluble and membrane-bound cytokines including lymphotoxin. B cells accumulate in lymphoid aggregates in RA synovium under the influence of a variety of chemotactic factors including CCL21 and B cell-attracting chemokine-1 (CXCL13).

A member of the TNF superfamily of cytokines known as B lymphocyte stimulator (BLyS, also called BAFF) has also been identified as a key molecule that regulates B cell

differentiation. BLyS binds to transmembrane activator and CAML interactor (TACI), which is present on both B and T cells. If this system is blocked using recombinant TACI-Ig to absorb the cytokine and a related B cell differentiation factor called APRIL, then the number of B cells is dramatically reduced and antibody production is decreased. The same construct is effective as a therapeutic agent in collagen-induced arthritis, a model that depends on autoantibody production.⁷⁷

BLyS is produced in RA synovium, especially by macrophages. Synovial lining type B synoviocytes can also release BLyS and can be induced by TNF and IFN- γ in vitro. APRIL is localized mainly to dendritic cells in synovial germinal centers. TACI-Ig, which binds both BLyS and APRIL, disrupts the germinal centers and decreases immunoglobulin receptors in SCID mice implanted with rheumatoid synovium.⁷⁸ One clinical trial using an anti-BLyS antibody demonstrated minimal benefit in patients with RA, although a second study showed efficacy. Improved benefit might be possible with a biologic that blocks both APRIL and BLyS, although early studies showed that TACI-Ig significantly decreases serum immunoglobulin concentrations but has limited efficacy in RA.⁷⁹

Synovial B Cell Maturation. B cells isolated directly from germinal centers of RA synovium demonstrate a heterogeneous pattern of V-gene usage and rearrangement. The majority of VH genes are not mutated, suggesting that they are recent immigrants from the peripheral blood and are activated locally. For RF-producing cells, shared mutations containing an identical sequence throughout the variable domain of immunoglobulins have been identified in synovial tissue.⁸⁰ Preferential utilization of a limited number of VH and DH gene segments and marked preference for a DH reading frame encoding particular hydrophilic residues have also been observed, consistent with antigen-related selection and maturation. Analysis of expressed heavy-chain variable domains supports the notion that the B cell response in RA synovium is oligoclonal. Similarly, B cell clones isolated from either RA synovium or bone marrow with “nurse-like” cells have limited VH usage.

B cells associated with follicular dendritic cells in the rheumatoid synovium can further differentiate and develop additional mutations, suggesting antigen-driven selection. Plasma cells in other areas of the synovium have distinct rearrangements compared with the B lymphocytes associated with dendritic cells. This raises the question of whether the plasma cells arise locally or migrate from the blood. Although plasma cell rearrangements are not always similar to the B cells, groups of plasma cells use similar genes, albeit with distinct mutations. Therefore the plasma cells could derive from synovial B cell clones that mutated and whose progeny proliferate and differentiate.

What is not certain is whether this process represents an ectopic lymphoid organ performing normal functions or whether it is related to autoimmunity. The presence of abundant autoantibody-producing cells in the synovium supports the latter hypothesis, although normal immune responses might also occur in the joint. Cells that produce RFs, anti-type II collagen antibody, and ACPA populate the RA synovium.

Maturation and survival of B cells depend on stromal cells and cells with nurselike properties that support

lymphocyte maturation in the thymus. The synovium of patients with RA also contains nurselike cells, which can increase expression of CD40 and class II MHC proteins on B cells. B cell survival is supported by this population of cells, whereas autoreactive clones evade deletion and produce autoantibodies. A variety of cytokines including GM-CSF, IL-6, and IL-8 are produced by RA nurselike cells, and direct contact with B cells is critical for maximal proliferation and antibody production. Of interest, cultured B cells spontaneously migrate beneath ordinary FLS, which permits them to survive *in vitro* for prolonged periods of time. The process depends on the interaction of the integrin $\alpha 4/\beta 1$ on B cells with synoviocytes expressing CD106 (VCAM-1). Interference with the B cell–synoviocyte interaction decreases B cell survival and is one potential mechanism by which therapeutic interventions targeted at integrins might suppress autoreactivity and inflammation in RA.

B Cell Depletion in RA. Although the role of T cells and cytokines attracted most of the scientific interest in recent years, clinical trials with an anti-CD20 antibody (rituximab) demonstrating efficacy in RA refocused investigators on B cells and autoantibodies. The precise function of CD20 is not well defined; it is expressed on mature B cells but not plasma cells. Rituximab causes a rapid and profound depletion of peripheral blood B cells. In mice, anti-CD20 antibody depletes B cells in blood, spleen, lymph nodes, and bone marrow. The few remaining B cells in the spleen were of the B1 but not B2 phenotype. Peritoneal B cells are only partially depleted, suggesting that some sites are privileged and protect B cells despite adequate drug penetration.

In RA, serial synovial biopsies demonstrate partial B cell depletion after rituximab therapy despite the virtual absence of peripheral B cells. The clinical responses do not always correlate closely with the extent of synovial depletion, although some patients with the most impressive responses appear to have marked declines in the number of B cells in the post-treatment specimens. Surprisingly, B cell depletion does not consistently decrease autoantibody production or cytokine production in the synovium, nor does a change in ACPA or RF levels predict a clinical response.⁸¹ Longer-term biopsy studies suggest that plasma cells are decreased in synovium 24 weeks after the treatment with rituximab and that this correlates with decreased symptoms.

B Cell Contribution to Synovitis. The simplest explanation for B cell contributions to RA lies in their ability to produce autoantibodies and differentiate into long-lived plasma cells. However, autoantibody titers do not correlate well with disease activity and RA-associated antibodies are detected in individuals without evidence of synovitis. The synovial biopsy data on synovial autoantibody production also suggest that B cells play a more complex and nuanced role in the disease. For example, plasma cells might be a more relevant source of autoantibodies than CD20⁺ B cells.

Perhaps more important, B cells are potent antigen-presenting cells that could serve this function either in the inflamed synovium or in central lymphoid organs. In an SCID mouse model using rheumatoid synovial explants, T cell activation, lymphopoiesis, and cytokine production

depended on B cells.⁸² In the same model, treatment with TACI-Ig to inhibit APRIL and BLyS decreased synovial inflammation and IFN- γ production in tissues with germinal centers.

B cells can also make a variety of cytokines including LT α , TNF, and IL-6. Although macrophages and synoviocytes might produce greater amounts of proinflammatory factors, production by B cells in strategic locations in the joints and elsewhere might help drive synovitis. A novel subset of regulatory B cells, like regulatory T cells, could decrease inflammatory responses in RA through the production of suppressive cytokines like IL-10 and TGF- β . It is not clear how B cell depletion might select for specific B cell subsets, and it is possible that the regulatory B cells could be relatively enriched.

Dendritic Cells

Dendritic cells (DCs) are potent antigen-presenting cells that populate synovial tissue and synovial effusions of patients with RA. DCs generally sample the environment, especially at mucosal and skin surfaces; process antigens; and then migrate to a central lymphatic site where they present the antigens to T cells. An emerging appreciation of DC function in the etiology of RA led to the concept that the cells could be loaded with local autoantigens and migrate to central lymphoid tissues, where they can participate in the initiation of disease. DCs are also potent producers of type I interferons, which has been implicated in numerous autoimmune diseases such as lupus and RA.

Rheumatoid synovium could function like lymphoid tissues in some circumstances with mature DCs expressing CD86, CD83, and DC-LAMP localized in perivascular lymphocytic infiltrates and aggregates. Ultrastructural analysis of the synovium shows the DCs in contact with lymphocytes, where they can present antigens. The presence of DCs is not unique to RA and has been identified in other inflammatory arthritides including gout and spondyloarthropathies.

DCs are recruited to synovium, like other immunocompetent cells, through the generation of chemotactic factors and expression of the appropriate adhesion molecules. The subsequent localization with the synovium and the formation of microarchitecture such as lymphoid aggregates also depends on production of chemokines in the synovial environment. DCs express the chemokine receptor CCR7, which usually permits them to home to lymphoid tissue and orchestrate organization into the appropriate germinal centers. Synoviocytes in RA express two CCR7 ligands (CCL19 and CCL21), which provide a signal for the DCs to remain in the peripheral tissue. Immature DCs and plasmacytoid DCs are also scattered throughout the synovial sublining region. B cell–enriched lymphoid follicles, which are usually organized around follicular DCs (FDCs), are also found in some RA joint tissues. The source of FDCs is not well defined, but cultured FLS can perform FDC functions *in vitro* and could contribute *in vivo* as well. Synoviocytes derived from RA patients can bind to germinal-center B cells and suppress B cell apoptosis.

Follicular DC–containing ectopic lymphoid structures in rheumatoid synovium also express high levels of

activation-induced cytosine deaminase, a key gene that participates in immunoglobulin class switching. ACPA-positive plasma cells surround these aggregates, suggesting that the aggregates play a role in autoantibody production. The architecture and ACPA-positive cells persist when tissue is transplanted into SCID mice. Therefore synovial DCs not only help organize the microarchitecture of synovial tissue but also participate in the development of high-affinity IgG autoantibodies.⁸³

Cytokines in the rheumatoid synovium such as GM-CSF influence the proliferation and maturation of DCs. Increased numbers are found in the tissue and synovial effusions, where they comprise up to 5% of mononuclear cells. RA synovial tissue DCs do not always behave normally. For example, IL-10 suppresses dendritic cell function, in part by decreasing expression of CD86 and class II MHC molecules. However, RA dendritic cells isolated from the joint are resistant to this effect, possibly because they express lower amounts of the IL-10 receptor.⁸⁴ Aside from presenting antigens, DCs also produce cytokines that can influence T cell differentiation in the joint including IL-12 and IL-23, which can enhance the bias toward the Th1 and Th17 (see later) phenotypes; APRIL, which enhances B cell survival; and, as noted earlier, interferons.

Mast Cells, Polymorphonuclear Leukocytes, and Natural Killer Cells

Mast cells are present in the synovial membranes of patients with RA and, in some patients, are located at sites of cartilage erosion. Rheumatoid synovial membranes contain more than 10 times as many mast cells than do control synovial samples from patients undergoing surgery for meniscectomy. Mast cells and histamine are also found in a majority of synovial fluid specimens from inflammatory synovitis. A detailed analysis of several indicators of proliferation and the enumeration of synovial mast cells has demonstrated strong positive correlations between the number of mast cells in synovial tissue and the degree of lymphocyte infiltration.⁸⁵ Mast cells from RA synovium express significantly higher amounts of the C5a receptor, compared with OA synovium.

Resident mast cells in synovium respond to cytokines that stimulate mast cell growth and chemotaxis. Extracts of mast cells can induce adherent rheumatoid synovial cells to increase production of PGE₂ and collagenase, and immunostaining of RA synovial mast cells demonstrates tryptase and TNF. Mast cell–derived heparin has significant effects on connective tissue. In particular, it may modulate the effects of hormones on osseous cells and thereby alter the balance of bone synthesis toward degradation.

The role of mast cells in the initiation phase of synovitis was highlighted in the passive K/BxN model in which their absence prevented disease.⁸⁶ It is not certain if the cells are required once synovial inflammation has been established and other cell types such as neutrophils supplant the mast cells in some circumstances. For instance, the production of leukotriene B₄ in the same model requires neutrophils but not mast cells in established disease. Treatment of synovial tissue explants cultures with a c-Kit tyrosine kinase inhibitor that blocks stem cell factor signaling and decreased

production of TNF.⁸⁷ These data suggest that mast cells might contribute to synovial cytokine production in established disease.

More intriguing, recent data suggest that preformed IL-17A is present in granules of synovial mast cells in RA (Figure 69-9).⁸⁸ The conventional view of IL-17 is that it mainly comes from activated T cells. Cultured mast cells released the IL-17 when stimulated with TNF or immune complexes. There is also a correlation between the presence of IgE and FcR1ε and mast cell degranulation in rheumatoid synovium. More direct evidence of mast cell involvement in RA comes from an open label clinical trial using the c-Kit inhibitor masitinib in RA, where evidence of clinical efficacy was observed. c-Kit is a receptor tyrosine kinase that binds to stem cell factor and facilitates mast cell growth and survival.

Despite the abundance of neutrophils in RA synovial effusions, only rare polymorphonuclear leukocytes (PMNs) infiltrate the synovium. NK cells have, however, been identified in RA synovium.⁸⁹ Cytotoxic NK cells contain large amounts of granzymes, which are serine proteases. One potentially important immunoregulatory role of NK cells is that they can stimulate B cells to produce RFs. A subset of NK cells that express large amounts of CD56 are unusually abundant in RA synovial tissue and fluid.⁹⁰ These cells could potentially produce cytokines or enhance proinflammatory cytokine production by T lymphocytes and macrophages. There is little information on invariant natural killer T cells (iNKT), which respond to lipid antigens. However, blocking CD1d and iNKT function decreases severity of collagen-induced arthritis in mice.

Bone Marrow Cells

Although most attention has been directed at the synovium, cartilage, and cortical bone in RA, the subcortical bone and bone marrow also contribute to synovial inflammatory responses. Primitive bone marrow mesenchymal cells can traverse cortical bone through pores in murine collagen-induced arthritis before the onset of clinical disease, take up residence in the synovium, and produce mediators that enhance synovitis.⁹¹ This process is TNF dependent and is abrogated in mice that lack TNF receptors. CD34⁺ mesenchymal cells in rheumatoid bone marrow are more highly activated as judged by their NFκB status and their ability to differentiate into fibroblast-like cells that produce MMPs and proangiogenic factors.

Bone marrow can also contribute other relevant cells including macrophage lineage cells that migrate to the synovium and nerselike cells that support the survival of B cells. Just as the bone marrow can influence the synovium, the reverse is also true. Invasive pannus can rupture through cortical bone and invade the marrow space in some patients. When this occurs, B cell aggregates are especially prominent in the marrow and occur in an environment rich in B cell chemoattractants such as CCL21 and B cell survival factors such as BlyS.

The bone marrow changes in RA could be either secondary to synovitis or a primary event (Figure 69-10).⁹² The most common explanation for RA is that synovitis occurs first and that it expands into the marrow through

Figure 69-9 Interleukin-17A (IL-17A) in mast cells as a source of IL-17A in rheumatoid arthritis (RA). Traditional paradigms suggest that IL-17 is mainly produced by Th17 cells in the RA synovium. However, mast cells can also produce this cytokine. Immunostaining studies showed that preformed IL-17 could be detected in mast cell granules in RA synovium. Note that the combination image on the right demonstrates IL-17A (green) colocalizing with the mast cell marker (red). This suggests a pivotal role of mast cells in the inflammatory response. MCT, mast cell tryptase. (From Hueber AJ, Asquith DL, Miller AM, et al: Mast cells express IL-17A in rheumatoid arthritis synovium, *J Immunol* 184:3336, 2010.)

soluble factors and direct extension (“outside-in” hypothesis). The notion that bone marrow reactivity might be a primary event and that the activated cells migrate directly to the synovium through cortical bone or via the bloodstream has received increasing attention (“inside-out” hypothesis).

The role of the bone marrow in the pathogenesis of RA is suggested by immunohistologic studies of marrow showing mature B cells and activated T cells forming aggregates, as in the rheumatoid synovium.⁹³ Functional changes also occur including the ability of marrow mesenchymal cells of RA patients to support B and T cell survival and the production of IL-6 and TNF by marrow cells. Bone marrow mesenchymal cells from RA patients induce B cell growth and support the survival of T cells. Nurselike cells can also be grown from marrow, and marrow monocytes can induce RF production in vitro. There is considerable cross-talk between the synovium and the bone marrow, perhaps via the circulation, diffusion of soluble mediators, or direct migration of cells through cortical pores. The bidirectional interactions between the synovium and the bone marrow suggest that both “inside-out” and “outside-in” mechanisms can participate in RA.

Neural Elements and Rheumatoid Synovium

The synovium in RA is richly innervated with somatic afferent fibers, C-fibers that detect pain, and sympathetic neurons. In addition to providing information to the central nervous system (CNS) on the state of the synovium, peripheral nerves profoundly influence synovial inflammatory responses.⁹⁴ For instance, neuropeptides such as substance P and vasoactive intestinal peptide can activate macrophages, increase vascular permeability, and modulate T cell phenotype. Sympathetic fibers can enhance or suppress inflammation depending on the site and timing of stimulation by modulating adrenergic tone. Although vagal branches have not been detected, their primary neurotransmitter acetylcholine is detected in tissues and can suppress synovial cytokine production through the $\alpha 7$ nicotinic receptor. Perhaps most interesting, spinal cord circuits can directly modulate synovial inflammation. Activation of adenosine receptors in the spinal cord or inhibition of spinal p38 can markedly decrease synovial inflammation in joint destruction in rat arthritis models. Intrathecal etanercept also blocks peripheral inflammation almost as well as systemic administration of the TNF blocker.⁹⁵

Figure 69-10 Initial synovial lesion in rheumatoid arthritis (RA). Although traditional paradigms suggest that it begins as a synovial disease, the initial insult could be at a distant site. The figure depicts two possible scenarios: (1) RA begins in the synovium and then extends into the bone and bone marrow, and (2) the initial lesion is in the bone marrow, which can extend into the synovium as cells migrate through cortical pores or through the bloodstream. (From Schett G, Firestein GS: *Mr Outside and Mr Inside: classic and alternative views on the pathogenesis of rheumatoid arthritis*, *Ann Rheum Dis* 69:787, 2010.)

Synovitis in Early versus Late Rheumatoid Arthritis

Although the synovium during the first few weeks of symptomatic RA occasionally demonstrates a paucity of lymphocyte infiltration, endothelial cell injury, tissue edema, and neutrophil accumulation, in general it has a histologic appearance similar to long-standing disease. The extent of lymphoid aggregation, T cell infiltration, and synovial-lining hyperplasia can resemble chronic disease even when symptoms have been present for a short period of time. The cytokine patterns of these biopsies as determined by immunohistochemical analysis indicated similar levels of T cell (such as IFN- γ) and non-T cell factors (such as IL-1 and TNF). The tumor suppressor gene *p53* is also expressed in early RA, most likely due to intense oxidative stress in the environment.

Biopsies of asymptomatic joints from patients with early or late RA also have lymphocyte infiltration, cytokine production, and *p53* expression. Although IFN- γ , IL-1, and TNF levels are increased compared with normal synovium, they are modestly lower than in clinically active joints. Some cytokines such as IL-8 and the number of macrophages are higher in the painful joints. Macrophage and plasma cell infiltration in early RA might predict more erosive or severe disease. In animal models of arthritis, increased synovial inflammation and expression of proinflammatory transcription factors such as activator protein-1 (AP-1) and NF κ B also occur well before clinically evident arthritis.⁹⁶

These studies suggest that patients with “early” RA, as defined by the duration of symptoms, might, in fact, already have chronic disease and that evaluation of truly early disease might require assessment of patients long before the onset of symptoms (if this is even possible). The observation that autoantibodies are produced in RA patients years before the clinical arthritis also supports the notion that a preclinical phase can possibly precede symptomatic synovitis. In addition, profiling cytokine and chemokine levels in stored serum samples of patients who ultimately develop RA show increased levels of chemokines and cytokines, especially in the ACPA-positive population. This reinforces the concept that RA is a continuum that can progress to clinical synovitis. However, the time lines and the environmental stimuli that cause progression are not known.

Animal Models as Surrogates for Rheumatoid Synovitis

Animal models of RA are crucial to understand the biology of synovitis. However, they are an imperfect representation at best for this uniquely human disease. The specific inciting agents are known, the time course is compressed, and disease is induced in genetically pure strains. Despite many differences between various models and human disease, there are many similarities for pathogenic influences such as the presence of autoantibodies and, in many cases, the cytokine profile.⁹⁷

The time course for cytokine and signal transduction activation is an important variable when interpreting therapeutic interventions. For example, IL-6 gene expression is high during a relatively narrow window in collagen-induced arthritis (Figure 69-11).⁹⁸ Activation of signaling molecules such as the MAP kinases in the synovium also follows

patterns that are similar to, but not identical to, RA. These issues do not invalidate the value of the models, but they do provide context for understanding why so many interventions are effective in preclinical studies but fail in human clinical trials.

SYNOVIAL FLUID AND THE SYNOVIAL FLUID CARTILAGE INTERFACE

KEY POINTS

RA synovial effusions contain neutrophils and mononuclear cells.

Immune complexes that contain autoantibodies such as RFs or anticitrullinated protein antibodies can fix complement, leading to the generation of chemoattractants.

Small molecule mediators of inflammation such as prostaglandins and leukotrienes are present in RA synovial fluid.

Figure 69-11 Kinetics of synovial activation in collagen-induced arthritis. Although there are many similarities between mouse models and rheumatoid arthritis (RA), the time course of the former is highly compressed and the pathogenic mechanisms might differ. The figure shows the time course for activation of synovial p38 MAP kinase (**A**) and IL-6 gene expression (**B**) in the mouse model. Note that IL-6 expression is high during a relatively limited period of time. The pattern of kinase activation also does not precisely correlate with clinical disease (**C**). Understanding the time course and pathogenic events of mouse models and how they relate to RA will help with interpretation of the preclinical model. (From Fukushima A, Boyle DL, Corr M, Firestein GS: Kinetic analysis of synovial signalling and gene expression in animal models of arthritis, *Ann Rheum Dis* 69:918, 2010.)

Synovial effusions accumulate in the joints of most patients with active RA due to a substantial increase in fluid influx that cannot be removed despite an increase in lymphatic flow. There is an inverse relationship between the molecular weight of proteins and their concentrations in minimally inflamed synovial fluid. High-molecular-weight serum proteins gain access more easily to synovial fluid in inflamed joints, and the relatively high concentration of IgG in RA synovial fluid is good evidence for local synthesis of immunoglobulins. Markedly increased permeance of proteins in rheumatoid patients is also evidence of the severe microvascular lesion in rheumatoid synovitis. Newer techniques evaluating the synovial fluid proteome in RA using mass spectroscopy might provide new insights into the key mediators. More than 400 proteins in RA effusions were identified as potential biomarkers of disease activity including C-reactive protein and six members of the S100 family of calcium granule binding proteins.⁹⁹ In general, assays for autoantibodies or assessments of exudate versus transudate in synovial fluid have little value; the concentration of serum proteins in effusions is usually about half to two-thirds the level in the blood.

Polymorphonuclear Leukocytes

Large numbers of PMNs accumulate in rheumatoid synovial effusions and enter via postcapillary venules in the synovium. Neutrophils adhere to activate synovial microvasculature due to their abundant surface expression of selectins and the β_2 integrins. After adherence, chemotactic agents produced by endothelium and resident synovial cells facilitate exit from the intravascular space into the tissue. Thus considering the survival time of PMNs in synovial fluid, an average rheumatoid effusion containing 25,000 PMNs per mm^3 could exceed 1 billion cells each day. The ultimate fate of these cells is usually apoptosis. Neutrophil survival requires expression of the forkhead transcription factor FOXO30.¹⁰⁰ Mice that lack this gene are resistant to inflammatory arthritis due to shortened PMN life span.

High concentrations of chemotactic agents in the synovial fluid in RA recruit a large number of cells to the intra-articular cavity. Few PMNs are seen in the synovium itself; once in the tissue they move rapidly to the synovial fluid, drawn by agents such as C5a generated due to complement activation, leukotriene B₄ (LTB₄), platelet-activating factor, and chemokines. CXC chemokines including ENA-78 and IL-8 is especially abundant in synovial fluid and can attract neutrophils into the intra-articular space. RA PMNs can also release chemokines such as macrophage-inflammatory protein-3 α (MIP-3 α) into the milieu that promote migration of additional cells into the joint space.

Once in the joint, neutrophils engage immune complexes through Fc receptors, especially FcR γ I and FcR γ III, that activate spleen tyrosine kinase (Syk). This process initiates a signaling cascade that includes the MAP kinases and NF κ B, cytoskeletal reorganization, release of granule content, generation of reactive oxygen and nitrogen species, and enhanced phagocytosis. Many of the cells contain immune complexes within phagosomes that include IgG and IgM along with RF and complement proteins such as C1q, C3, and C4. PMNs from synovial fluid in RA release de novo synthesized proteins including matrix proteins such as fibronectin, neutral proteinases, and IL-1. Neutrophils also secrete IL-1Ra and oncostatin M, a member of the IL-6 family. Although the amount of IL-1Ra each neutrophil produces is low compared with macrophages, the sheer number of PMNs allows them to produce large amounts in synovial effusions.

Neutrophil cells also release numerous proteases that can adversely affect the lubricating properties of synovial fluid and the integrity of the cartilage including elastase and trypsin. Neutrophil collagenase (MMP-8) can digest native collagen in cartilage, which then makes it susceptible to degradation by other MMPs such as the stromelysins. Although synoviocytes are generally considered major producers of the MMPs, animal models of arthritis suggest that neutrophil-derived proteases play a significant role in cartilage damage.

Although difficult to assess in humans, animal models demonstrate a role for neutrophils in the inflammatory processes. The passive K/BxN and collagen-induced arthritis models, which depend on autoantibodies to bind to the cartilage and fix complement, require neutrophils for full expression of the disease. Depleting neutrophils with antibodies almost completely prevents synovial inflammation in these models. In the K/BxN model, neutrophils also initiate vascular permeability that permits pathogenic antibodies to gain access to the joint space.

Synovial Fluid Lymphocytes

The lymphocyte subsets in synovial fluid differ from that of peripheral blood and synovial tissue. Even though synovial effusions contain an abundance of T cells, the CD4-to-CD8 ratio is actually reversed compared with that of blood or synovial tissue, with an excess of CD8⁺ cells relative to CD4⁺ lymphocytes. In addition, synovial tissue is nearly devoid of neutrophils, which often constitute 50% to 75% of synovial fluid cells. The percentage of regulatory T cells (CD4⁺CD25⁺) is also higher in synovial fluid than peripheral blood.

Synovial fluid contains T cells, which express high levels of surface HLA-DR antigens. Surface activation antigens are increased on synovial fluid lymphocytes including VLA-1 and CD69. Of CD4⁺ cells in rheumatoid synovial fluid, most are memory cells and express CD45RO on their surface. Despite the activated phenotype, synovial fluid T cell function is usually deficient compared with peripheral blood cells. For instance, synovial fluid lymphocyte proliferation in response to mitogens or most recall antigens such as tetanus toxoid is significantly less than paired blood T lymphocytes. Mycobacterial antigens and the 60-kD HSP are exceptions because proliferation is actually greater in synovial fluid cells, perhaps because they can also activate TLRs. Cytokine production by synovial fluid T cells in vitro is also low including mitogen-induced expression of IFN- γ and IL-1.

Defective T cell responses by RA synovial fluid mononuclear cells could be due to anti-inflammatory cytokines such as IL-1Ra and TGF- β .¹⁰¹ Nonspecific components of joint effusions such as hyaluronic acid can be toxic and indirectly suppress T cell activation. The mechanism of diminished T cell activation could also be due to defective TCR signaling. Articular T cells have diminished tyrosine phosphorylation of proteins after stimulation, especially the key signal transduction pathway p38 MAP kinase. Furthermore, tyrosine phosphorylation of the TCR ζ chain, an early event in TCR signaling, is low compared with peripheral blood T cells. The hyporesponsiveness of synovial fluid T cells correlates with a significant decrease in the levels of the intracellular redox-regulating agent glutathione.¹⁰² Restoration of intracellular glutathione increases proliferation of RA synovial fluid T cells. Therefore oxidative stress in the inflamed environment can suppress antigen-specific T cell responses.

Platelets and Platelet Microparticles

Platelets are a rich source of growth factors and cytokines including platelet-derived growth factor (PDGF). They are present in rheumatoid synovial effusions and can form microparticles. This process is dependent on collagen receptor glycoprotein VI. The microparticles activate cultured synoviocytes and, through an IL-1-dependent mechanism, stimulate cytokine secretion. Platelet depletion also suppresses arthritis severity in animal models.

Intra-articular Immune Complexes and Complement Fixation

Synovial Fluid Immune Complexes

Complexes containing immunoglobulins are abundant in the blood and synovial fluid of patients with RA, especially containing IgM. The most prevalent antigens in these aggregates contain IgG complexed with RF due to their ability to bind the Fc portion of immunoglobulin. Using more sensitive techniques, circulating immune complexes in RA contain up to 20 polypeptides including albumin, immunoglobulin, complement, type II collagen, fibrinogen, and acute-phase reactants, as well as DNA. These complexes can potentially fix complement, releasing

chemotactic peptides and factors that activate neutrophils and other inflammatory cells.

Immune Complexes Embedded in Cartilage

The aggregates of RF, IgG, and various peptides become embedded into cartilage and other tissues in contact with synovial fluids. Electron microscopic studies demonstrate immunoglobulin complexes with damage to the cartilage matrix in the microenvironment. Immune complexes are absent under areas of cartilage invaded actively by synovial pannus, suggesting that phagocytic cells in the invasive synovium bind to and ingest the immune complexes. This possibility lends credence to the notion that immune complexes deposited in the avascular superficial layers of cartilage in the joint may serve as chemoattractants for the pannus. Immune complexes have been extracted from cartilage of RA and OA patients. Rheumatoid cartilage contains more than 40-fold more IgM and more than 10-fold more IgG than healthy cartilage extracts. IgM RF is found in the majority of RA cartilage extracts but not in OA or healthy control extracts. In addition, more than 60% of the RA cartilage extracts are positive for native and denatured collagen type II antibody.

Synovial Fluid Complement

Biologically active products of complement activation accumulate in synovial fluid during acute inflammation. This observation led to the concept that RA represents an intra-articular immune complex disease. This was the prevailing view of RA until the role of T cells and cytokine networks emerged in the 1980s.

The liver is the major source of complement synthesis in humans, and passive transfer of serum proteins into effusions accounts for many of the complement proteins found there. However, synovial tissue also actively produces complement proteins. Macrophages and fibroblasts produce complement proteins under the influence of cytokines such as IFN- γ , IL-1, and TNF. In situ hybridization shows that C2 is expressed in the synovial intimal lining, whereas C3 appears to be produced by synovial sublining macrophages. Analysis of synovial tissue shows that all complement genes from the classic pathway are expressed in RA, as well as in healthy synovium.

Despite the local production of complement components, the activities of C4, C2, and C3 and total hemolytic complement in rheumatoid synovial effusions are lower than in synovial fluids from patients with other joint diseases. Although the most prominent evidence of activation implicates the classic pathway, cleavage products of the alternate pathway including factor B and properdin have also been documented in RA. IgM RF appears to be a more important determinant of complement activation than IgG RF in serum and synovial fluid. Accelerated catabolism of C4 in RA and the presence of C4 fragments in the plasma correlate with titers of IgM RF.

The interactions between PMNs and the complement system are substantial. Neutrophil lysosomal lysates contain enzymes that cleave complement proteins and generate chemotactic activity such as C5a from serum. C5a, in addition to being a principal chemotactic factor in inflammatory

effusions, mediates lysosomal release from human PMNs and induces cytoskeletal rearrangement. The chemotactic anaphylatoxins C3a and C5a are often present in rheumatoid effusions, as are the terminal complement components that comprise the C5b-C9 membrane attack complex. The latter is especially interesting because low levels of the complex can activate synoviocytes in vitro.

Targeting Complement in Rheumatoid Arthritis

Inhibiting complement proteins has obvious therapeutic potential in RA. In addition to theoretic considerations and evidence of complement consumption, a polymorphism in or near the C5 locus has been associated with increased risk of RA. For instance, intra-articular treatment with a soluble complement receptor (sCR1) inhibits joint swelling in rat antigen-induced arthritis. C5-deficient mice have decreased joint inflammation in collagen-induced arthritis and the passive K/BxN model. Absence of C3 or factor B also inhibits collagen-induced arthritis. Unlike the C5 knockout mice, which have normal antibody responses, the C3- and factor B-null animals have lower levels of anti-type II collagen antibodies. The role of C3 convertase has been explored in more detail using transgenic mice that produce the regulatory protein complement receptor 1-related gene/protein γ (Crry). These mice have no obvious phenotype and are not more susceptible to infection. However, collagen-induced arthritis is suppressed in the Crry transgenic mice.

These data suggest that classic and alternative complement pathways participate in RA. A humanized anti-C5 antibody has been evaluated in a placebo-controlled study. The antibody inhibits C5 activation and function of the C5b-C9 attack complex. Although the monoclonal antibody was well tolerated, there was only modest evidence of clinical efficacy. Similarly, a C5a receptor antagonist did not decrease inflammation in a short-term placebo-controlled synovial biopsy study even though the compound was effective in preclinical models and blood levels were in the therapeutic range.¹⁰³ C5 alone is not sufficient to sustain inflammation in the rheumatoid joint and it probably participates in a redundant inflammatory network. It is not clear whether targeting other complement components such as C3 convertase would be more successful.

Arachidonate Metabolites

Prostaglandins

Arachidonic acid metabolites are produced in the inflamed joint via oxidation by cyclooxygenases (COX) to prostaglandins and thromboxanes or by lipoxygenases to leukotrienes. COX inhibitors are clearly effective in RA, although the effect is modest and is due, in part, to spinal analgesic action. Animal models of arthritis are variably sensitive to prostaglandin; indomethacin almost completely prevents adjuvant arthritis in rats but has minimal benefit in collagen-induced arthritis in mice. This serves as a reminder that results in rodent models do not always correlate with human disease.

Stable prostaglandins, especially PGE₂, produce vasodilation, increase vascular permeability, and are involved centrally in fever. They also display some anti-inflammatory

activities that could account for limited efficacy. For example, the drug misoprostol, a prostaglandin analogue, has modest but significant anti-inflammatory or immunomodulatory effects. Physiologic concentrations of PGE₂ inhibit IFN- γ production by T cells, HLA-DR expression by macrophages, and T cell proliferation.

Production of prostaglandins in RA depends on both COX-1 and COX-2 (see Chapter 24). The former is constitutively expressed and is responsible for the normal endogenous production of prostaglandins in the joint, as well as in other tissues. COX-2, on the other hand, is an inducible enzyme responsible for increased prostaglandin synthesis in inflamed tissue. Cytokines such as IL-1 and TNF induce COX-2 gene expression by cultured synovio-cytes and macrophages. COX-2 mRNA and immunoreac-tive protein are increased in RA synovium.¹⁰⁴ Most nonsteroidal anti-inflammatory drugs including indometha-cin and ibuprofen inhibit both enzymes. Much of the anti-inflammatory activity and analgesia in RA results from inhibition of COX-2. Targeting prostaglandin receptors such as E2 or E4 is an alternative approach that might have less deleterious effects on the gastric mucosa and cardiovas-cular disease. More recent data suggest that EP4 can also act on DCs and T cells to enhance production of Th1 and Th17 cells.¹⁰⁵

Prostaglandin I₂, like PGE₂, can also contribute to syno-vial inflammation. For instance, mice lacking the prosta-glandin I₂ receptor have significantly decreased arthritis severity in the collagen-induced arthritis model compared with wild type mice even though they make similar amounts of anticollagen antibodies.

Leukotrienes

LTBs are a potent proinflammatory produced by neutrophils and chemotactic for neutrophils, eosinophils, and macro-phages. They also promote neutrophil aggregation and adherence to endothelium. Peripheral blood PMNs from rheumatoid patients have an enhanced capacity for LTB₄ production compared with normal individuals.¹⁰⁶ In murine collagen-induced arthritis, LTB₄ antagonists decreased paw swelling and joint destruction, suggesting a pivotal role for this potent chemoattractant. Surprisingly, LTB₄ blockade has minimal efficacy in RA.

Anti-Inflammatory Arachidonic Acid Metabolites

Certain arachidonic acid metabolites such as 15-deoxy-delta(12,14)-PGJ(2) can bind to peroxisome proliferators, activate receptors (PPARs), and inhibit cytokine produc-tion and inflammation in animal models of arthritis. Cyclo-pentenone prostaglandins can also inhibit NF κ B by blocking one of the key enzymes that activates this pathway, namely I κ B kinase- β (IKK β). Lipoxins and resolvins represent a unique class of lipid mediators that help resolve inflamma-tory diseases. Lipoxins (LX) have a trihydroxytetraene structure and are produced from arachidonic acid via the lipoxygenase pathways. LXA₄ binds with high affinity to a G protein-coupled receptor denoted lipoxin A₄ receptor (ALXR). Activation of ALXR inhibits recruitment of neu-trophils by attenuating chemotaxis, adhesion, and transmi-gration into tissues and by diminishing chemokine and

cytokine production. LXA₄ significantly decreased cytokine and MMP expression in FLS through an NF κ B-dependent mechanism.

PERIPHERAL BLOOD LYMPHOCYTE IMMUNE RESPONSES

Although peripheral lymphocytes are the most accessible, many investigators believe there is greater value studying cells isolated from the primary site of disease. The number of CD4⁺ helper T cells is mildly increased in the circulation of patients with RA, with a concomitant decrease in CD8⁺ lymphocytes (and an increased CD4-to-CD8 ratio). The surface phenotype of circulating T cells in RA suggests activation in some studies, but not in others. For instance, an increased percentage of $\alpha\beta$ and $\gamma\delta$ TCR-bearing cells might express HLA-DR and the adhesion protein VLA-4 ($\alpha_4\beta_1$ integrin). The latter is especially critical in that VLA-4 plays an important role in the recruitment of cells to the synovium through interactions with VCAM-1 on endothelial cells. Other markers of activation are not neces-sarily elevated on RA T cells in the circulation. Therefore peripheral-blood T cells express some, but not all, pheno-typic characteristics of activation. It is not clear whether this process occurs in the peripheral or central lymphoid organs or whether cells are activated in the synovium and re-enter the circulation via the synovial lymphatics.

Immunoregulatory dysfunction has been described in RA peripheral lymphocytes. One of the early observations was the inadequate control of EBV-infected B lymphocyte growth due to a defect in T cell function in RA. The abnor-mal T cell response could be correlated somewhat with disease activity, but it was also noted that the abnormality was present in T cells of some patients with inflammatory arthropathies other than RA.¹⁰⁷ IFN- γ and IL-2 production is significantly suppressed in these RA lymphocyte cultures under certain conditions.

T cell diversity and maturation are abnormal in RA. Whereas thymic output normally decreases with age, this process appears to be accelerated in RA.¹⁰⁸ The presence of T cell receptor rearrangement excision circles (TREC) is a measure of thymic release of mature T cells. Using this parameter, the thymic output in RA may decline prema-turely. Similarly, telomere attrition suggests inappropriate “aging” of the T cells. This could be due to a primary defect in peripheral T cell homeostasis or due to impaired thymic function with increased T cell turnover due to chronic immune stimulation. This concept is supported by the observation that telomeric length in RA T cells is shorter than in normal controls and more closely resembles older populations.

Activated B lymphocytes are also present in the periph-eral blood of patients with RA. The number of circulating B cells that spontaneously produce RF and other autoanti-bodies is significantly higher in RA compared with normal individuals. B cells that are enriched in autoantibody production are characterized by a surface determinant CD5. This antigen is normally expressed by T cells, but it is also displayed by fetal B cells and a small number of immature B cells in adults. RA patients with normal circulating numbers of lymphocytes show an abnormal

kappa-to-lambda-chain analysis compared with controls, implying oligoclonal B cell proliferation. It is not known whether this reflects expansion of the restricted number of clones capable of producing RF or whether an inciting antigen is something other than IgG and related specifically to RA. On the other hand, normal and RA peripheral blood B cells have equal numbers of B cells that produce IgM anti-type II collagen antibodies. The B cells that accumulate in the synovial fluid, however, produce IgG antibodies that are more likely to be pathogenic.

Attempts to characterize the gene expression profiles in the peripheral blood cells of patients with RA have met with mixed results. In some cases, RNA transcripts can potentially distinguish between RA and psoriatic arthritis and include differential expression of tumor suppressors, MAP kinases, and other proinflammatory proteins. Other limited subsets of genes have been proposed as markers for disease activity or to predict response to targeted therapy. However, additional confirmatory studies are necessary to determine whether these patterns are consistent.

ROLE OF T CELL CYTOKINES

KEY POINTS

Several subsets of T cells have been implicated in the pathogenesis of RA.

Relatively low levels of T cell cytokines are present in RA synovium.

The T cell cytokines that are present, such as IFN- γ and IL-17, can be produced by Th1 cells or Th17 cells.

Regulatory T cell function, which suppresses activation of other T cells, might be low in RA synovium.

The contribution of T cells to synovial inflammation can be through antigen-independent mechanisms such as direct cell-cell contact with macrophages.

The cytokine milieu in RA is rich in factors produced by many cell lineages. Factors produced by T lymphocytes are surprisingly low in RA, whereas those generated by macrophages and by synovial fibroblasts are markedly increased (Table 69-5). The production and contribution of T cell-derived cytokines can be examined based on functional lymphocyte subsets.

T Helper Type 1 Cell Cytokines

Extensive investigation into the cytokine profile of RA suggest a bias toward the Th1 phenotype, which produces cytokines such as IL-2 and IFN- γ and expresses the chemokine receptors CXCR3 and CCR5. Many T cell clones derived from RA synovial tissue produce a Th1 cytokine pattern. Considerable data have accumulated on the relative abundance and function of the prototypic Th1 cytokine, interferon- γ (IFN- γ), which is the most potent inducer of HLA-DR antigens. IFN- γ also induces adhesion molecules on the surface of endothelial cells and can help recruit inflammatory cell accumulation at sites of injury. One of the

most important functions of IFN- γ is its capacity to alter the balance of extracellular matrix synthesis and degradation by decreasing collagen synthesis and inhibiting matrix metalloproteinase (MMP) production by cytokine-stimulated cultured FLS.¹⁰⁹

Relatively low concentrations of IFN- γ have been detected in RA joints, well below the amounts needed to induce HLA-DR expression on monocytes. The relative lack of IFN- γ in rheumatoid joints has been observed at the level of mRNA using a variety of techniques.

Immunohistochemical analysis clearly demonstrates IFN- γ in small numbers of RA synovial T cells, although the percentage is far less than in chronically inflamed tonsils.

Another major Th1 cytokine, IL-2, is a T cell–derived cytokine that serves as an autocrine or paracrine T cell growth factor. Although it was originally reported to be present in synovial fluid using biologic assay, more specific immunoassays showed that IL-2 is detected in only a small percentage of RA synovial effusions and synovial tissues and, when present, is only found in low concentrations.¹¹⁰ TNF, GM-CSF, and IL-6 can be expressed by Th1 and Th2 cells. All three are abundant in synovial fluid and produced by RA synovial tissue. However, the primary sources of these cytokines in the rheumatoid joint are macrophages and fibroblasts rather than T cells.

Targeted therapeutics to block Th1 function or recruitment to RA synovium is an attractive concept. Several CCR5 antagonists have been developed because this chemokine receptor serves as a binding protein for HIV and might be used to decrease Th1 cytokine levels in the joint. Some of these have demonstrated efficacy in animal models of arthritis. However, the role of IFN- γ is actually quite complex because administration of the cytokine does not exacerbate disease and, if anything, results in improvement in some patients. IFN- γ knockout mice or IFN- γ receptor deficiency can exacerbate collagen-induced arthritis in mice and serve as a reminder that the effects of cytokines can be highly variable depending on the model and timing of expression.

T Helper Type 2 Cell Cytokines

Although relatively low levels of Th1 cytokines are readily detected, Th2 cytokine levels are exceedingly low in RA. Using immunoassays, IL-4 and LT α are generally not detected in RA synovial fluid. In situ hybridization also shows little or no IL-4 mRNA in RA synovial tissue. When sensitive nested reverse-transcriptase polymerase chain reaction (RT-PCR) techniques are used on synovial biopsies, Th2 cytokines IL-4 and IL-13 are absent in RA, whereas both IFN- γ and IL-12 (a cytokine that induces T cell maturation toward the Th1 phenotype) are usually present. The Th2 cytokine IL-10, which has potent anti-inflammatory activities, is expressed in RA synovium. However, macrophages rather than T cells are the major producers in RA. Some data suggest that synovial fluids in early synovitis have high concentrations of Th2 cytokines such as IL-4 and IL-13 and that this pattern distinguishes patients who progress to RA. As the disease evolves in these patients, the Th2 signature diminishes.¹¹¹

T Helper Type 17 Cytokines

The proinflammatory cytokine produced by Th17 cells, IL-17, exists as six isoforms (IL-17A through F). IL-17A and, to a certain extent, IL-17F mimic many of the activities of IL-1 and TNF with respect to FLS function including induction of collagenase and cytokine production. IL-17A is present in modest, but functionally relevant, concentrations in RA synovial effusions.¹¹² More important, T cell–derived IL-17A in synovial tissue can synergize with IL-1 and TNF by activating synoviocytes to produce matrix

MMPs and other proinflammatory cytokines. IL-17 receptors IL-17RA and IL-17RC are expressed by synoviocytes and, when engaged, can activate the transcription factor NF κ B and initiate an inflammatory cascade. In addition to its effect on mesenchymal cells, IL-17 can participate in bone erosion by enhancing osteoclast activation. Bone resorption in an in vitro model using synovial explants and bone shows that blockade of IL-17, IL-1, and TNF is more effective than blocking the individual factors.

Immunohistochemistry initially suggested that IL-17 is mainly present in sublining T cells, although it could also be derived from mast cells. In some studies, IL-17 is present in the synovium of a minority of RA patients. Because immunoreactive IL-17 can be detected near the erosive front of pannus, it could also participate in extracellular matrix destruction. Animal models of arthritis demonstrate that IL-17 inhibition is anti-inflammatory and protects animals from bone and cartilage destruction.¹¹³ IL-1, IL-23, and/or TGF- β in the joint can potentially enhance Th17 cell differentiation, although the precise cytokine environment for this process in humans and mice can differ. BlyS also has the potential to enhance Th17 cell differentiation and promote inflammatory arthritis. All of these cytokines are present in RA synovium, thereby providing an excellent milieu to enhance the generation of these cells.

The role of the IL-17 family is clear in animal models of arthritis, where blocking IL-17A in particular has dramatic effects on inflammation and matrix destruction. The data in humans are less robust, perhaps because the segregation of human T cells into clear subsets is not as well defined. Early clinical studies with anti-IL-17A antibodies in RA are encouraging, although the benefit is modest compared to TNF inhibitors.¹¹⁴

Regulatory T Cells (Tregs)

The role of classically defined inducible regulatory T cells (CD4⁺CD25⁺CD127⁺) in RA remains poorly defined. Deficiency of this subset, which produces IL-10 and TGF- β and regulates other T cells through cell contact, could contribute to autoimmunity. Studies of RA peripheral blood demonstrate normal numbers of Tregs, although the CD4⁺CD25⁺ subset appears to accumulate in rheumatoid synovial effusions. However, peripheral blood Treg responses in vitro to stimuli such as anti-CD3 and anti-CD28 antibody displayed an anergic phenotype and were unable to suppress T cell or monocyte cytokine production. Of interest, this abnormality might be reversed when patients are treated with TNF inhibitors.¹¹⁵ The effect of treatment on synovial Tregs was also observed in a synovial biopsy study. The number of FoxP3⁺ cells was relatively low in T cell infiltrates identified in rheumatoid synovial biopsies. Interestingly, the number decreased further after intra-articular injection with corticosteroids.¹¹⁶

These data suggest that abnormal Treg function could be secondary to cytokine imbalance in RA rather than a primary event. Treatment can have a significant effect on the number and function of Tregs, which makes evaluation of their role in patient samples difficult to interpret. Nevertheless, enhancing or restoring Treg activity as a therapeutic intervention could potentially downregulate other T cells and cytokine production.¹¹⁷

Enhancing the number or activity of Tregs has been used to treat animal models of arthritis. Antigen-induced arthritis is exacerbated when CD4⁺CD25⁺ cells are depleted and suppressed when they are passively transferred to affected animals. Treg function is low in some inflammation models.¹¹⁸ Methotrexate also increases Treg function in collagen-induced arthritis. Administration of neuropeptides such as vasoactive intestinal peptide (VIP) appears to suppress collagen-induced arthritis by enhancing the Treg function in synovium and lymph nodes.

T Helper Cell Cytokine Imbalance in RA

The relative abundance of Th1 cells suggests that the synovium resembles a Th1-like delayed-type hypersensitivity reaction and/or a Th17 autoimmune environment. Th2 cytokines and cellular responses that normally suppress Th1 activation are nearly absent, thereby raising the possibility that the lack of T cell activation along the Th2 pathway in RA contributes to disease perpetuation. For example, addition of exogenous IL-10 or IL-4 to cultures of synovial tissue cells or synovial tissue explants suppresses synthesis of proinflammatory cytokines and MMPs by cultured RA synovial tissue explants.¹¹⁹ The inhibitory action of IL-4 might be mediated by decreased c-Jun and c-Fos expression, which is required for efficient production of MMPs and cytokines. In addition, IL-10 and IL-4 increase the release of other anti-inflammatory cytokines such as IL-1Ra by synovial cells. Although IL-10 protein is present in RA synovial fluid and the gene is expressed by synovial tissue cells,¹²⁰ in vitro studies of cultured synovial cells suggest that not enough IL-10 is produced to suppress IFN- γ production.

The notion that Th1 and Th17 cytokines initiate and perpetuate arthritis, whereas Th2 cytokines are suppressive, is supported by studies in animal models. For instance, IL-4 and IL-10 were administered individually or in combination in collagen-induced arthritis.¹²¹ The cytokines had modest or no benefit when used separately, but together the effect was impressive. Clinical improvement correlated with decreased synovial IL-1, TNF, and cartilage destruction. Anti-IL-10 antibody therapy in collagen-induced arthritis accelerates disease. The complexity of cytokine networks in inflammatory arthritis is underscored by studies on the role of IL-12 in collagen-induced arthritis. In early arthritis, IL-12 administration increases the incidence of collagen-induced arthritis, whereas anti-IL-12 is beneficial.¹²² However, in late disease, IL-12 administration suppresses arthritis and anti-IL-12 causes an exacerbation. As noted above, administration of anti-IL-17A antibody to block the prototypical Th17 cytokine has only modest benefit. Alternative approaches that inhibit both IL-17A and F β , such as soluble receptor constructs, might increase efficacy. The role of Th17 cells is clearer in other inflammatory diseases, most notably psoriasis, where IL-17A blockade demonstrates a robust response.¹²³

Although the notion that enhancing Th2 cytokines is attractive, a clinical trial using IL-10 in RA did not demonstrate significant clinical benefit or improvement in histologic evidence of synovial inflammation.¹²⁴ It is possible that combinations of Th2 cytokines will be required to coordinate a maximum effect.

Activation of Synovial Cells by Cell-Cell Contact with T Lymphocytes

Even though T cell activation is relatively modest in rheumatoid synovium, direct cell-cell contact permits these cells to participate in synovial cytokine networks and matrix destruction. Membranes prepared from activated T cells can directly stimulate macrophages and FLS to produce cytokines and MMPs.¹²⁵ The membrane constituents that regulate this process vary, depending on the particular culture conditions, but include adhesion molecules such as LFA-1 and membrane-bound TNF. Hence a T cell displaying these proteins can potentially contribute to macrophage and fibroblast activation in an antigen-independent fashion. One of the best-characterized consequences of this pathway is the ability of T cells to enhance synovial macrophage TNF production in a contact-dependent manner after exposure to macrophage-derived IL-15.¹²⁶

The concept that lymphocytes can activate cells in the environment through direct contact suggests an unanticipated role for T cells in RA. The traditional paradigm assumes that T cells in the joint respond to a pathogenic stimulus and subsequently drive an antigen-specific response. However, cell-cell contact influences can be antigen-independent and only require colocalization of memory T cells with synoviocytes or macrophages. Because T cells with a memory phenotype accumulate into the joint due to the release of chemoattractants, there is no requirement for a specific arthritogenic antigen to initiate the process. Instead, activation of innate immunity by nonspecific stimuli permits subsequent ingress of the correct T cell phenotype to engage resident synovial lining cells. The combination of adaptive immune responses and antigen-independent stimulation could contribute to the diversity of individual responses to targeted therapy and the relative paucity of complete remissions.

ROLE OF MACROPHAGE AND FIBROBLAST CYTOKINES

KEY POINTS

Macrophage and fibroblast cytokines are abundant in RA synovium.

Cytokine networks involve proinflammatory cytokines such as IL-1, TNF, IL-6, IL-15, IL-18, GM-CSF, and IL-33. These and many other factors help perpetuate synovial inflammation.

Chemokines that recruit inflammatory cells into the joint are commonly produced by macrophages and fibroblasts.

Anti-inflammatory cytokines such as IL-1Ra and IL-10 are produced in rheumatoid synovium, although in amounts insufficient to suppress proinflammatory cytokine function or production.

Virtually every macrophage and fibroblast proinflammatory mediator investigated in the RA synovium is abundant. In this section, some of the major cytokines and effectors produced in the joint are described, with an emphasis on the prevalence of macrophage and fibroblast products as

major forces that perpetuate RA. Macrophages, in particular, are the most vigorous producers of cytokines. The role of macrophage and fibroblast cytokines in the pathogenesis of RA was initially suggested by studies involving patient samples, as well as preclinical experiments in animal models.

Proinflammatory Macrophage and Fibroblast Cytokines

Interleukin-1 Family

The IL-1 family is a ubiquitous group of polypeptides with a wide range of biologic activity; they include IL-1 α , IL-1 β , IL-18, IL-33, and IL-1Ra, which is a natural inhibitor of IL-1 (see [Suppressive Cytokines and Cytokine Antagonists](#) later for a description of IL-1Ra). Abundant animal data indicate that IL-1 can serve as a key regulatory factor in inflammatory arthritis. For instance, recombinant IL-1 β induces the accumulation of PMNs and mononuclear leukocytes in the joint space and the loss of proteoglycan from articular cartilage when injected directly into rabbit knee joints. Transgenic mice that overexpress IL-1 also develop inflammatory arthritis, whereas mice that lack the natural IL-1 antagonist IL-1Ra have increased susceptibility to collagen-induced arthritis. In most cases, IL-1 blockade in animal models modestly decreases synovial inflammation while markedly diminishing bone and cartilage destruction.

Interleukin-1. Synovial macrophages are the most prolific source of IL-1 in the joint, and nearly half of all macrophages in the RA synovium express IL-1 β .¹²⁷ Immunohistologic studies confirm this, with especially abundant IL-1 protein in synovial lining macrophages adjacent to type B synoviocytes and in sublining macrophages near blood vessels. The IL-1 in the lining can subsequently activate type B synoviocytes to proliferate and secrete a variety of mediators. A broad range of stimuli are capable of inducing IL-1 production by macrophages; for example, immunoglobulin Fc fragments and, to a lesser extent, immune complexes, can generate IL-1 production by rheumatoid synovial macrophages. Collagen fragments can induce IL-1 production, and type IX collagen, which has been found only in articular cartilage and localized into intersections of collagen fibrils, is a potent inducer of IL-1 by human monocyte.

Within the rheumatoid joint, IL-1 induces fibroblast proliferation; stimulates the biosynthesis of IL-6, IL-8, and GM-CSF by synovial cells; and enhances collagenase and prostaglandin production. It increases glycosaminoglycan release in human synovial fibroblast cultures, although the effect of IL-1 on the production of intact proteoglycan molecules by intact articular cartilage explants can be the opposite. IL-1 induces a number of adhesion molecules on FLS and endothelial cells including VCAM-1 and ICAM-1 and enhances bone resorption.

IL-1 has been implicated in RA, and inhibition of this mediator using various IL-1 targeted biologic agents has modest anti-inflammatory activity. Even combinations of IL-1 and TNF-directed therapy does not provide benefit beyond TNF blockade alone.¹²⁸ In contrast, diseases with a

well-defined role for IL-1 such as Still's disease, familial cold autoinflammatory syndrome, Muckle-Wells syndrome, and crystal diseases such as gout have a much better clinical response. These data suggest that IL-1 plays a modest role in the clinical manifestations of RA. Its contributions to cartilage and bone destruction are still uncertain, but preclinical models suggest that the protective effects of TNF blockade are mediated through IL-1.

One explanation for the relatively modest benefit of IL-1 in RA relates to its signaling mechanisms. IL-1 activates NF κ B through the kinase MyD88, which is the same pathway as TLRs. When IL-1 signaling is blocked, it is possible that TLR ligands in the synovium including exogenous ones such as peptidoglycan or endogenous ones such as heat shock proteins can provide the stimulus required to overcome IL-1 blockade. This concept was tested in the passive K/BxN model where mice lacking the IL-1 receptor had markedly decreased arthritis severity. When small amounts of the TLR4 ligand lipopolysaccharide were administered, robust synovitis ensued. If a similar system occurs in RA, then IL-1 blockade would be unable to control synovitis as long as TLR signaling remains intact.

Interleukin-18. In addition to IL-1 α and IL-1 β , a homologous protein in the IL-1 family known as IL-18 has been implicated in RA. This cytokine was originally defined by its ability to bias the immune response toward the Th1 phenotype, especially in the presence of IL-12. In collagen-induced arthritis, IL-18 inhibition significantly attenuates disease.¹²⁹ Of particular interest, the same effect was observed in IFN- γ knockout mice, indicating that other non-Th1-related activities of IL-18 might be important. Subsequent studies showed that IL-18 induces GM-CSF, nitric oxide production, and TNF expression by synovial macrophages. IL-18 is expressed by RA synovial tissue, especially by synovial fibroblasts and macrophages, and its production is markedly increased by TNF and IL-1 β . A natural inhibitor, the IL-18 binding protein can potentially be used as a therapeutic agent to block both the proinflammatory effects and pro-Th1 effects of IL-18. One potential concern for IL-18 as a target for RA is the fact that the IL-1 convertase inhibitor had only modest benefit. IL-18, like IL-1 β , is processed by this enzyme in order to produce biologically active cytokine. Therefore an IL-1 convertase inhibitor theoretically should block both IL-1 β and IL-18 release by macrophages.

Interleukin-33. IL-33 is a novel cytokine that signals through the ST2 surface receptor. Like high-mobility-group box 1 (HMGB1), it is an "alarmin" that provides a danger signal due to tissue damage and necrosis with release of intracellular contents. Blocking IL-33 decreases inflammation in several animal models of arthritis including collagen-induced arthritis and antigen-induced arthritis. Mast cells are activated by IL-33 and can subsequently release their content. Thus mast cell-dependent models such as passive K/BxN are less severe in ST2^{-/-} mice.¹³⁰ More intriguing, its ability to trigger mast cells could play a role in the release of mast cell products such as TNF and IL-17A in RA synovium. IL-33 can also bias T cells toward the Th2 phenotype, so the fact that it is expressed in RA synovium and synovial effusions raises some questions about its precise function in long-standing disease.

Tumor Necrosis Factor

The TNF superfamily is an extended group of related genes that play a major role in inflammation, immune responses, cell survival, and apoptosis. At least 19 members of the family have been identified, with TNF identified as the eponymous member. Each cytokine has its own preference for cell surface receptor, although there is some promiscuity of receptor binding and functional overlap. The TNF superfamily members exhibit conserved amino acid sequences, suggesting a single ancestral gene. Many include type II membrane protein characteristics and can be released from cell surfaces after proteolytic cleavage. A C-terminal conserved domain called the TNF-homology domain is also shared by several superfamily members. The active forms of the proteins are homotrimers, except for LT α and LT β , which can form either heterotrimers or homotrimers. Several members have been discussed earlier in the relevant sections. In this section, one of the “founding” members of the superfamily is discussed due to its critical role in synovial inflammation.

TNF is a pleiotropic cytokine that has been implicated as a key proinflammatory cytokine in RA and detected in rheumatoid synovial fluid and serum. It is produced as a membrane-bound protein that is released from the cell surface after proteolytic cleavage by TNF convertase, a membrane MMP. IL-1 and TNF have many similar activities including the ability to enhance cytokine production, adhesion-molecule expression, proliferation, and MMP production by cultured synoviocytes. In some systems, the effects of these two agents are synergistic. Although they share many functions and signal transduction pathways, IL-1 and TNF use distinct surface receptors and intracellular signaling pathways.

The efficacy of TNF inhibitors in RA demonstrates its critical role in the disease; heterogeneity of the rheumatoid process is also apparent because only about one-third of patients have a dramatic response to TNF inhibitors. Efficacy requires continuous therapy because cessation typically leads to a flare of disease. Perhaps more interesting, evidence is beginning to accumulate, suggesting that early aggressive therapy with anti-TNF agents can induce long-term remissions even after therapy is withdrawn. This exciting notion suggests that interventions in the earliest stages of disease could prevent the establishment of chronic synovitis.

TNF, like IL-1, stimulates collagenase and PGE₂ production by human synovial cells, induces bone resorption, inhibits bone formation in vitro, and stimulates resorption of proteoglycan and inhibits its biosynthesis in explants of cartilage. In situ hybridization and immunohistochemical studies show that TNF is primarily produced by synovial macrophages in RA.

Animal models have also supported the general role played by TNF in inflammatory arthritis. For instance, overexpression of TNF in transgenic mice leads to an aggressive and destructive synovitis. In fact, the arthritis also spontaneously occurs in transgenic mice that express only a membrane-bound form of TNF on T cells.¹³¹ TNF blockade is an effective anti-inflammatory agent in many animal models of arthritis,¹³² although the effects on bone and cartilage destruction are less prominent than with IL-1

inhibitors and are likely mediated through downstream inhibition of IL-1 production.

TNF inhibition in RA significantly decreases extracellular-matrix destruction as measured by radiographic progression.¹³³ It is not clear why the bone-protective effects are more prominent in humans than in the animal models. TNF blockade is also more effective in animal models when combined with an IL-1 inhibitor, supporting the additive or synergistic relationship between the two cytokines in animal models. However, this has not been observed in RA.

The mechanism of action for TNF blockers is distinct from other biologic agents. For instance, individuals with an inadequate response to a TNF inhibitor are still likely to respond to either rituximab or abatacept. This supports the notion that multiple independent pathways can contribute to the pathogenesis of RA and the heterogeneous nature of the disease. Surprisingly, clinical responses do not always correlate with protection of the extracellular matrix. Patients with little or no clinical improvement in signs and symptoms of RA still have significant delay or arrest of joint damage. This observation supports the contention that inflammation and destruction could have distinct pathogenic mechanisms such as inhibition of osteoclast maturation, even though synovial inflammation continues unabated.

Interleukin-6 Family

IL-6 is a complex cytokine produced by many cell types including T cells, monocytes, and FLS. Originally defined by its B cell-stimulating properties, it induces immunoglobulin synthesis in B cell lines, is involved in the differentiation of cytotoxic T lymphocytes, and is a major factor in the regulation of acute-phase response proteins like C-reactive protein by the liver. The IL-6 receptor includes a common chain (gp130) that is shared with other cytokines and an IL-6-specific chain (IL-6R). IL-6R can be shed from cell surfaces, bind to IL-6, and deliver it to cells that lack IL-6 receptors by combining with gp130. IL-6 signaling proceeds through the Janus kinases (JAKs), especially JAK1, and phosphorylation of STAT3.

A striking correlation between serum IL-6 activity and serum levels of acute-phase reactants such as C-reactive protein, α_1 -antitrypsin, fibrinogen, and haptoglobin occurs in patients with RA. Very high levels of IL-6 are present in RA synovial fluid, and synovial cells in culture from diverse inflammatory arthropathies produce IL-6. In situ hybridization of synovial tissue also shows IL-6 mRNA in the intimal lining, and immunohistochemistry studies show IL-6 protein in the lining and sublining regions. Although many synovial macrophages express the IL-6 gene, the majority of IL-6 appears to be produced by type B synoviocytes.

The pivotal role of IL-6 in RA has been demonstrated by clinical trials using a monoclonal antibody that binds to IL-6R. The clinical responses are similar to TNF inhibitors including protective effects on bone and cartilage damage.¹³⁴ Surprisingly, IL-6R antibody is also effective in patients who have not responded to TNF blockade. This observation is surprising considering that TNF is considered upstream of IL-6 in the cytokine cascade and that TNF inhibition markedly decreases IL-6 levels in RA. Neutropenia, increased

liver enzymes, and altered blood lipids have been observed with IL-6 inhibition, although the relative importance of these observations is still uncertain. JAK inhibitors have also demonstrated efficacy in RA; this might be due, in part, to the effect on IL-6 signaling.

Cytokines with structural similarity to IL-6 and that share surface-receptor subunits have also been implicated in RA. Several of these, IL-11, leukemia inhibitory factor (LIF), and oncostatin M, are expressed by rheumatoid synovium and can be detected in synovial effusions. The biologic effects of these factors are complex and can be either protective (e.g., by increasing expression of protease inhibitors such as tissue inhibitors of metalloproteinase [TIMP]) or proinflammatory (e.g., by increasing expression of chemokines or MMPs) depending on the culture conditions or the specific model evaluated. This dichotomy among the family members is demonstrated by the fact that IL-11 administration ameliorates collagen-induced arthritis, whereas antibodies to oncostatin M are protective.

Interleukin-12 Family

The IL-12 family includes a group of cytokines that play a key role in the differentiation of T cells and inflammation. IL-12 is a heterodimeric cytokine with two subunits (e.g., p35 and p40) encoded on separate genes and produced by antigen-presenting cells. IL-23 and IL-27 have similar heterodimeric structures to IL-12, with p29/p40 and p28/EB13 components, respectively. In the context of antigen presentation, IL-12, IL-23, and IL-27 can bias T cell responses toward the Th1 phenotype. IL-23 can also play a pivotal role in the production of Th17 cells, along with IL-1 and TGF- β . The IL-12 family of cytokines are generally produced by macrophages in the rheumatoid joint but are also produced by other antigen-presenting cells such as dendritic cells. Although clinical data defining the role of these cytokines are still lacking, there are anecdotal case reports of RA patients with malignancy treated with recombinant IL-12 developing a flare of disease. Animal models including adjuvant arthritis in rats and collagen-induced arthritis in mice are partially ameliorated by neutralization of IL-12, IL-23, or IL-27 depending on the timing of treatment. In some situations, however, IL-27 has anti-inflammatory effects.

Interleukin-15

IL-15 is an IL-2–like cytokine that regulates numerous immunologic functions relevant to RA including T cell chemotaxis and proliferation, production of immunoglobulins by B cells, and the generation of NK cells. Although IL-15 can serve as an IL-2–independent mechanism for activating T cells, its role in RA may be related to its key role in TNF regulation. Macrophages are the primary source of IL-15 in RA, and the cytokine is able to induce a cell-contact mechanism of macrophage TNF production that requires T cells. Although T lymphocytes, or at least their membranes, are required for this process, the macrophages actually produce the TNF. This network provides a potential mechanism whereby local IL-15 production in the synovium can lead to autocrine production of TNF in a T cell–dependent but antigen-independent fashion. IL-15 has

been demonstrated in RA synovial macrophage cells. Soluble IL-15 receptors can function as an IL-15 inhibitor, and when used in vivo can decrease joint inflammation in collagen-induced arthritis. Preliminary clinical trials in RA using an anti-IL-15 antibody had a signal for efficacy, although probably not sufficient to continue developing this particular biologic agent.¹³⁵

Interleukin-32

IL-32 is a novel cytokine that activates NF κ B and induces the production of several proinflammatory cytokines and chemokines including TNF, IL-1, IL-6, and IL-8. It has been implicated in Crohn's disease by virtue of its ability to markedly enhance caspase 1 activation and IL-1 production in cells that have been exposed to muramyl dipeptides. More recently, IL-32 was demonstrated by immunohistochemistry in synovial tissues of patients with RA, especially in synovial-lining macrophage-like cells.¹³⁶ The level of IL-32 expression correlated with the presence of other cytokines implicated in RA including TNF, IL-1, and IL-18. Injection of IL-32 into the joints of naïve mice causes a robust transient synovitis. The synovial response could be partially abrogated by anti-TNF antibodies, suggesting that IL-32 induces this cytokine in vivo. These data suggest that IL-32 might be upstream from several proinflammatory mediators in RA and could represent a therapeutic target.

Colony-Stimulating Factors

Granulocyte-macrophage colony-stimulating factor (GM-CSF) supports the differentiation of bone marrow precursor cells to mature granulocytes and macrophages. As with other major colony-stimulating factors, GM-CSF also participates in normal immune responses. It is a potent macrophage activator including the induction of HLA-DR expression, IL-1 secretion, intracellular parasite killing, and priming for enhanced release of TNF and PGE₂. Neutrophil function is also regulated by GM-CSF, which enhances antibody-dependent cytotoxicity, phagocytosis, chemotaxis, and the production of oxygen radicals.

RA synovial fluid contains GM-CSF, which is produced by RA synovial tissue cells.¹³⁷ The major source in the synovium is macrophages, although IL-1– or TNF-stimulated FLS also express the GM-CSF gene. Its ability to induce HLA-DR gene expression on macrophages might be of particular importance in RA. GM-CSF, not IFN- γ , is the major DR-inducing cytokine in RA synovial effusions. Collagen-induced arthritis in mice is less severe in animals that lack a functional GM-CSF gene or are treated with anti-GM-CSF antibody, which supports the hypothesis that GM-CSF is an important proinflammatory mediator. Anti-GM-CSF antibodies are in clinical development. However, there is some concern that pulmonary alveolar proteinosis might be an adverse event because GM-CSF–deficient mice and autoimmune diseases marked by spontaneous production of anti-GM-CSF antibodies develop this syndrome. A recent phase IIa clinical trial demonstrated potential clinical benefit from an anti-GM-CSF antibody in RA, although long term efficacy and safety still must be evaluated.

Macrophage colony-stimulating factor (M-CSF) is also expressed by RA synovium and is present in synovial

effusions. Its primary pathogenic role in RA probably relates to its osteoclast-differentiating capacity. This factor cooperates with RANKL to facilitate bone erosions.

Chemokine Families

Chemokines are a family of related chemoattractant peptides that, with the assistance of adhesion molecules, summon cells into inflammatory sites. They are generally divided into families including CC, CXC, and CX3C based on the position of characteristic cysteine residues.

Many chemokines have been identified in the rheumatoid joint. IL-8, a CXC chemokine that was originally characterized as a potent chemoattractant for neutrophils, along with immune complexes and other chemotactic peptides such as C5a, contributes to the large influx of PMNs into the joint. Immunohistochemical analysis of synovial tissue demonstrates IL-8 protein in sublining perivascular macrophages, as well as in scattered lining cells.¹³⁸ Cultured synovial tissue macrophages constitutively produce IL-8, and FLS express the gene if they are stimulated with IL-1 or TNF. IL-8 accounts for about 40% of the neutrophil chemoattractant activity in synovial fluid. In addition, IL-8 activates neutrophils through G protein-coupled receptors and is a potent angiogenesis factor.

Many other chemoattractant proteins are implicated in RA. Macrophage-inhibitory protein-1 α , macrophage-inhibitory protein-1 β , macrophage chemoattractant protein-1 (MCP-1), and regulated on activation, normally T cell expressed and secreted (RANTES)—members of the CC subfamily—are produced by RA synovium, as are many other CC chemokines.

CXCL16 and epithelial neutrophil-activating peptide-78 (ENA-78) are CXC chemokines and are also abundant along with many others in that family.¹³⁹ The former, which binds to CXCR6 on T cells, can contribute to the recruitment of lymphocytes into the synovium. ENA-78 accounts for about 40% of the chemotactic activity for neutrophils in RA synovial fluid. Concentrations of these chemokines are higher in RA synovial effusions compared with noninflammatory arthritides such as OA. Although the chemokines can also be detected in the blood, the levels are considerably lower than in the joint, thereby providing a gradient that signals cells to migrate into the synovium.

As noted earlier, lymphocyte-specific factors might contribute to the germinal center architecture of RA. The CXC factor B cell-activating chemokine-1 (BCA-1; CXCL13) binds to specific CXCR5 receptors on B cells. CXCL13 is expressed in the RA synovial tissues, especially by follicular dendritic cells in germinal centers and likely accounts for B cell migration to these regions.¹⁴⁰ CCL21 and several other factors participate in the anatomic organization of germinal centers, marginal zones, and other regions of lymphoid follicles. Another chemokine, SDF-1, is expressed by synoviocytes and endothelial cells and can play a major role as a chemoattractant for T cells in synovium via its receptor CXCR4. Unlike other chemokine receptors that can bind multiple members of the family, CXCR4 is highly specific for SDF-1 and is expressed by memory CD4⁺ lymphocytes.

Chemokines have attracted considerable attention as therapeutic targets in order to prevent recruitment of

immune cells into the synovium. Numerous preclinical models support the use of chemokine blockers. For instance, antibodies to fractalkine (CXCL3L1) suppress murine collagen-induced arthritis, even though anti-type II collagen antibody production was not affected.¹⁴¹ Anti-CXCL16 antibody also decreases clinical arthritis in the same model. One problem is that the system is highly redundant and several different chemotactic proteins can bind to the same receptor. No clinical improvement was observed in a study using anti-MCP-1 antibody, perhaps because the antibody also altered the kinetics of MCP-1 metabolism. Anti-IL-8 antibodies have met with limited success in psoriasis. More promising results were observed with antibody to IP-10 (CXCL10), which met its primary efficacy end point in a phase II study in RA.

Alternatively, chemokines bind to G protein-coupled receptors and can be targeted to block multiple factors. For instance, CCR1 antagonists, which blocks RANTES and MIP-1 α , has been evaluated in clinical trials.¹⁴² Although one compound significantly decreased synovial infiltration by CCR1-expressing cells, no significant improvement was observed. Chemokine receptor blockade has other levels of complexity such as CCR2-deficient mice, which develop more severe arthritis in some models. Several CCR2 antagonists, which block MCP-1, have not demonstrated significant efficacy in RA. These data suggest that the chemokine system including the receptors is both redundant, complex, and, in some cases, perhaps protective in arthritis.

Chemokines and other chemotactic factors (such as C5a and LTB₄) can signal through a variety of mechanisms, although many pathways converge on phosphoinositide-3-kinase (PI3K). Of the several PI3K isoforms, PI3K γ is relatively specific for chemokine signal transduction. This provides an opportunity to block multiple chemokine receptors simultaneously. Proof of concept for this approach was provided by studies in PI3K γ knockout mice, which have less synovial inflammation in passive and active collagen-induced arthritis than wild-type mice.¹⁴³ A small molecule PI3K γ inhibitor provided similar benefit. Therefore targeting shared intracellular pathways could potentially overcome some of the limitations presented by the complex chemoattractant system.

Platelet-Derived Growth Factor and Fibroblast Growth Factor

PDGF is a potent growth factor that is both chemoattractant and mitogenic for fibroblasts and induces collagenase expression. It is the most potent stimulator of long-term growth of synovial cells in culture. PDGF is expressed in vascular endothelial cells, platelets, and other synovial sublining cells in rheumatoid synovium, compared with healthy tissue. Multiple isoforms of this molecule have been identified (PDGF A through D), all of which have been detected in RA synovial membranes. PDGF D has been identified as an especially potent stimulator of MMP-1 expression in cultured synoviocytes. PDGF is a potent activator of the PI3K pathway, which leads to Akt phosphorylation and supports synoviocyte survival.

Fibroblast growth factors (FGFs) are a family of peptide growth factors with pleiotropic activities. In rheumatoid patients, it is likely that heparin-binding growth factor, the

precursor of acidic fibroblast growth factor, is a major mitogen for many cell types and stimulates angiogenesis. Interactions between FGF and proteoglycans is required for biologic activity. It is a potent angiogenic factor, inducing capillary endothelial cells to invade a three-dimensional collagen matrix and form capillaries. Synoviocytes can also be induced to increase expression of RANKL by FGF, thereby enhancing osteoclast activation and bone resorption. FGF is present in RA synovial fluid, and the genes are expressed by synovial cells. Synovial fibroblasts express FGF receptors and proliferate after exposure to the growth factor.

Suppressive Cytokines and Cytokine Antagonists

The proinflammatory cytokine network in RA is offset by a variety of suppressive and anti-inflammatory factors that attempt to reestablish homeostasis. Low production of these suppressive cytokines could potentially contribute to the perpetuation of the synovitis. Many cytokine antagonists or natural immunosuppressives represent potential therapeutic targets for the treatment of inflammatory diseases.

Interleukin-1 Receptor Antagonist

IL-1Ra is a naturally occurring IL-1 inhibitor that binds directly to types I and II IL-1 receptors and competes with IL-1 for the ligand-binding site. Interaction of IL-1Ra with the IL-1 receptors does not result in signal transduction, and, in contrast to IL-1 α or - β , the receptor-ligand complex is not internalized after it binds to the IL-1 receptor. Even though IL-1Ra has high affinity for the IL-1 receptor, it is a relatively weak inhibitor because IL-1 can activate cells even if only a small percentage of IL-1 receptors is occupied. Because of this, a substantial excess of the inhibitor is required to saturate the receptor and thereby block IL-1-mediated stimulation (usually 10- to 100-fold excess of IL-1Ra). Recombinant IL-1Ra inhibits a variety of IL-1-mediated events in cultured cells derived from the joint including the induction of MMP and prostaglandin production by chondrocytes and synoviocytes. It can block synovitis in rabbits induced by direct intra-articular injection of recombinant IL-1.

IL-1Ra is present in rheumatoid synovial effusions; much of it is produced by neutrophils and macrophages.¹⁴⁴ Immunohistochemical studies of rheumatoid synovium reveal IL-1Ra protein, especially in perivascular mononuclear cells and the synovial intimal lining. The IL-1Ra protein and mRNA can be detected in synovial macrophages and, to a lesser extent, in type B synoviocytes (Figure 69-12). The presence of IL-1Ra in synovium is not specific to RA because OA synovial tissue also contains IL-1Ra, albeit in lesser amounts. Normal synovium contains little, if any, IL-1Ra protein. Synovial cell culture experiments show that the amount of IL-1Ra is insufficient to antagonize synovial IL-1.

Interleukin-10

IL-10 is an immunosuppressive cytokine that was originally characterized as an inhibitor of T cell cytokine production. Its immunosuppressive actions might be important in pregnancy to suppress an immune response directed against

Figure 69-12 Localization of interleukin-1 receptor antagonist (IL-1Ra) messenger RNA in rheumatoid arthritis synovial tissue by in situ hybridization. The specific RNA transcript was detected in perivascular cells, especially macrophages. **A**, Bright field view. **B**, Same area using a dark field filter. Silver grains in the dark field view show the location of IL-1Ra-positive cells.

paternal MHC antigens, and it might regulate susceptibility to some parasitic infections. As noted previously, IL-10 protein is present in RA synovial fluid, and the gene is expressed by synovial tissue macrophages. Serial synovial biopsies in RA patients who were treated with recombinant IL-10 did not show any significant histologic improvement, and clinical responses were not impressive in a limited study.

Transforming Growth Factor- β

TGF- β is a key member of the TGF superfamily, which includes the bone morphogenic proteins that signal through intracellular signaling molecules known as *Smads*. It is widely distributed in different tissues and produced by many cells including T cells, monocytes, and platelets. It suppresses the production of collagenase and induces the expression of TIMP. TGF- β accelerates the healing of incisional wounds and induces both fibrosis and angiogenesis in experimental animal models. Substantial amounts of TGF- β are present in synovial fluid, although it is mainly present in an inactive, latent form, and the mRNA can be detected in RA synovial tissue.¹⁴⁵ Although typically considered an immunosuppressive cytokine with wound-healing properties, the role of TGF- β in RA is complex.

In RA, TGF- β is one of the factors responsible for blunted responses of T cells that have been exposed to synovial fluid. TGF- β also downregulates IL-1 receptor expression on some cell types including chondrocytes. When it is injected directly into the knees of animals,

fibrosis and synovial lining hyperplasia develop. In streptococcal cell wall arthritis, parenteral administration or systemic gene therapy with the TGF- β gene ameliorates the disease. However, intra-articular administration of anti-TGF- β antibody decreases arthritis in the injected joint but not in the contralateral joint in the same model. Although mainly considered anti-inflammatory, TGF- β also plays a key role in the development of autoimmunity through the differentiation of T cells into the Th17 phenotype.

Soluble Cytokine Receptors and Binding Proteins

Soluble cytokine receptors and binding proteins can absorb free cytokines and prevent them from engaging functional receptors on cells. Although these obviously could inhibit cytokine action, they also could act as carrier proteins that protect cytokines from proteolytic degradation or deliver them directly to cells such as the IL-6 receptor.

TNF receptors are normally expressed as membrane-bound proteins and can be released from the cell surface after proteolytic cleavage. Soluble p55 and p75 TNF receptors have been detected in RA synovial fluid, sometimes in high concentrations. Soluble TNF receptor levels can be considerably higher than the concentration of TNF in blood or synovial fluid and probably explain why biologically active TNF is difficult to detect in RA synovial fluid despite the presence of immunoreactive protein. Synovial membrane mononuclear cells have increased surface expression and mRNA levels of both TNF receptors compared with OA synovial tissue cells or peripheral blood cells.

Many other soluble receptors and binding proteins are produced in RA, albeit in concentrations too low to effectively suppress the proinflammatory cytokine milieu of the joint. For instance, the IL-1 type II receptor is present in RA synovial fluid, along with lesser amounts of the type I receptor. These soluble receptors can bind to IL-1 or IL-1Ra in synovial effusions. Soluble receptors to IL-15 and IL-17 have been characterized, and an IL-18 binding protein also can inhibit cytokine activity. In some cases, a soluble receptor can protect a cytokine from degradation or transport it to the cells, as with the IL-6 receptor.

Perpetuation of Synovitis by Macrophage-Fibroblast Cytokine Networks

Mapping the cytokine profile in RA led to targeted biologic therapy to inhibit cytokines and supports the concept that cytokine networks play a key role. The network pathway is not autonomous and, except for certain patients with very early disease, discontinuation of anticytokine therapy allows the disease to flare. Nevertheless, paracrine and autocrine cytokine networks in the synovial intimal lining contribute largely to inflammatory arthritis in RA (Figure 69-13).

Several cytokines that have been identified in the synovium or synovial fluid can participate in this system and might explain lining cell hyperplasia, HLA-DR and adhesion-molecule induction, and synovial angiogenesis. The list of potential candidates in this highly redundant system is extensive. Several of these including IL-1, TNF, and IL-6 now have well-defined roles. The first two, along with numerous other factors (e.g., IL-15, IL-18, IL-32) are

Figure 69-13 Cytokine networks in rheumatoid arthritis (RA). Paracrine and autocrine pathways can lead to activation of fibroblast-like and macrophage-like synoviocytes in the synovial intimal lining. Both positive (+) and negative (−) feedback loops are present, although in RA the former predominate. T helper type 1 (Th1) or Th17 cytokines can potentially enhance the network, whereas Th2 cytokines are suppressive.

produced by synovial macrophages and stimulate synovial fibroblast proliferation and secretion of IL-6, GM-CSF, and chemokines, as well as effector molecules such as MMPs and prostaglandins. GM-CSF, which is produced by both synovial macrophages and IL-1 β - or TNF-stimulated synovial fibroblasts, can, in turn, induce IL-1 secretion to form a positive feedback loop. GM-CSF, especially in combination with TNF, also increases HLA-DR expression on macrophages. Macrophage and fibroblast cytokines could also indirectly contribute to the evidence for local T cell and B cell activation including RF production. Newly implicated members of the macrophage-fibroblast cytokine network such as IL-33 can activate other cell lineages such as mast cells that have attracted increased attention in recent years.

The cytokine profile recruits other immune and inflammatory cells into the synovium through the production of chemokines that select specific cell lineages for admission and retention in the synovium. Many of these chemokines including the CXC and CC families are produced by macrophages and fibroblasts and attract neutrophils, macrophages, and specific subpopulations of T and B cells. The sublining chemokine profile including CCL13 and CCL20 helps organize these newly infiltrated cells into organized lymphoid structures in some patients. Other factors such as IL-12 and IL-23 differentiate CD4⁺ T cells into the Th1 phenotype to produce relatively small amounts of IFN- γ and other relevant cytokines. IL-1 and TGF- β produced mainly by the lining can, along with IL-23, support the production of Th17 cells that release the potent IL-17 family members into the local milieu. All of this occurs in the presence of inhibitor factors, soluble receptors, and binding proteins that are overwhelmed by the inflammatory drive. Other cytokines, such as RANKL and M-CSF, activate osteoclasts that remodel bone.

Even though they do not cause RA, per se, cytokines clearly orchestrate the rheumatoid process. For individual patients, the pivotal cytokine or cytokines that must be blocked could be different, and even this could vary with the stage of disease. Ultimately, understanding the genetic

predisposition, the environmental triggers, and the specific patterns of cytokine production could help determine the correct combination of cytokine inhibitors that will be effective.

SIGNAL TRANSDUCTION AND TRANSCRIPTION FACTORS

KEY POINTS

Complex intracellular signaling mechanisms regulate cytokine production and actions in RA synovium.

NFκB, MAP kinases, AP-1, JAK, Syk, and several other pathways are potential therapeutic targets in RA.

Intracellular signal transduction systems transmit information from the environment to the interior of a cell, which can then respond appropriately to stress. The remarkable diversity of signaling pathways and transcription factors provides a selective mechanism for orchestrating activation and repression for appropriate genes. Many of the inflammatory responses observed in RA synovium including the activation of cytokine, proteases, and adhesion-molecule genes can be traced to specific transcription factors and signal transduction pathways.

Nuclear Factor κB

NFκB is a ubiquitous transcription factor that plays a key role in the expression of many genes central to RA including IL-1, TNF, IL-6, and IL-8. NFκB normally resides as an inactive heterodimer or homodimer in the cell cytoplasm associated with an inhibitory protein called IκB that regulates the DNA binding and subcellular localization of NFκB proteins by masking a nuclear localization signal. Extracellular stimuli such as cytokines or TLR agonists initiate a signaling cascade leading to activation of two IκB kinases (IKKα and IKKβ), which phosphorylate IκB at specific NH₂-terminal serine residues. Phosphorylated IκB is then selectively ubiquitinated and degraded by the 26S proteasome. This process permits NFκB to migrate to the cell nucleus, where it binds its target genes to initiate transcription.

NFκB is abundant in rheumatoid synovium, and immunohistochemical analysis demonstrates p50 and p65 NFκB proteins in the nuclei of cells in the synovial intimal lining.¹⁴⁶ Although the proteins can also be detected in OA synovium, NFκB activation is much greater in RA because of phosphorylation and degradation of IκB in RA intimal lining cells. Nuclear translocation of NFκB in cultured FLS occurs rapidly after stimulation with many proinflammatory cytokines (e.g., IL-1, TNF, IL-17) or TLR ligands (e.g., peptidoglycan, LPS). NFκB is also a major survival factor for cells and is responsible for resistance to apoptosis in some cell lineages after activation. This is especially important in intestinal inflammation, where IKKβ deficiency can actually increase mucosal damage because the lack of NFκB can increase cell death.

The relevance of NFκB to inflammatory arthritis has been tested in several animal models. Synovial NFκB is

rapidly activated, often long before clinical arthritis is evident. Adjuvant arthritis in rats is ameliorated using intra-articular gene therapy with the dominant negative IKKβ construct that blocks the IKK pathway,¹⁴⁷ and streptococcal cell-wall arthritis is blocked with decoy oligonucleotides or a dominant negative IκB adenovirus. NFκB inhibition is associated with decreased synovial cellular infiltration, as well as increased apoptosis. The role of this transcription factor in murine collagen-induced arthritis has been demonstrated using selective IKKβ inhibitors, which suppress arthritis and joint destruction.

Activator Protein-1

Like NFκB, AP-1 regulates many genes implicated in RA including TNF and the MMPs. AP-1 activity can be induced by extracellular signals including cytokines, growth factors, tumor promoters, and the Ras oncoprotein. AP-1 includes members of the Jun and Fos families of transcription factors that form Jun homodimers, Jun-Jun heterodimers, or Jun-Fos heterodimers. Multiple Jun and Fos family members (c-Jun, JunB, JunD, c-Fos, FosB, Fra-1, Fra-2) are expressed in different cell types that mediate the transcription of both unique and overlapping genes. AP-1-driven gene expression is greatly enhanced when one of its components, especially c-Jun, is phosphorylated by the c-Jun N-terminal kinase (JNK).

AP-1 proteins and nuclear binding are elevated in RA synovium, especially in the nuclei of cells in the intimal lining layer.¹⁴⁸ c-Jun and c-Fos proteins are also expressed in the sublining inflammatory infiltrate, albeit to a lesser degree. Localization of AP-1 to the intimal lining correlates with the site where most protease and cytokine genes are overexpressed in RA. AP-1 proteins are usually not detected in normal synovium, although modest amounts have also been detected in OA.

Cytokines such as IL-1 and TNF and TLR ligands probably contribute to the activation of AP-1 in RA synovium. These factors are potent inducers of AP-1 nuclear binding in cultured FLS. The specific Jun family members that constitute AP-1 in synoviocytes have a clear effect on function. For instance, c-Jun increases the production of proinflammatory mediators, whereas JunD suppresses cytokine and MMP production.¹⁴⁹ AP-1 decoy oligonucleotides suppress collagen-induced arthritis and inhibit cytokine production by synovial tissue.

Mitogen-Activated Protein Kinases

MAP kinases, which are signal transduction enzymes activated in response to cellular stress, are composed of parallel protein-kinase cascades that regulate cytokine and MMP gene expression. There are three different families of MAP kinases known as JNK, p38, and extracellular signal-regulated kinase (ERK). MAP kinases phosphorylate selected intracellular proteins, including transcription factors, which subsequently regulate the expression of various genes by transcriptional and post-transcriptional mechanisms. MAP kinases are activated by phosphorylation at conserved threonine and tyrosine residues by a cascade of dual-specificity kinases. These are, in turn, activated by MAP kinase kinase kinases. The relative hierarchy

of the individual MAP kinases depends on the cell type and inflammatory stimulus.

The MAP kinases are widely expressed in synovial tissue and are activated in rheumatoid synovium. Phosphorylated ERK, p38, and JNK can be detected by immunohistochemistry or Western blot analysis. All three kinases and their upstream regulators are constitutively expressed by cultured FLS and can be activated within minutes after exposure to cytokines. They regulate production of proinflammatory cytokines and MMPs.

p38 inhibitors are effective anti-inflammatory agents in murine collagen-induced arthritis and rat adjuvant arthritis, possibly by decreasing the production of proinflammatory cytokines. In addition, p38 inhibitors block TNF and IL-6 production by cultured macrophages and synovio-cytes, as well as cultured synovial tissue cells. Spinal p38 also plays a major role in pain processing, and inhibitors have potential for analgesic, as well as anti-inflammatory, action. Recent studies suggest that p38 in the central nervous system can regulate peripheral inflammation because intrathecal administration of a p38 inhibitor suppresses inflammation and joint destruction in rat adjuvant arthritis.

Given the putative role of p38 in RA, it is surprising that clinical efficacy of the selective p38 inhibitors is modest, at best.¹⁵⁰ Clinical response rates are rarely greater than 40%, compared with the 60% range for TNF blockers. Perhaps more interesting, an initial decrease in acute-phase reactants is only transient despite adequate drug levels. The explanations for the dissociation among the animal, in vitro, and human data are uncertain, and it is clear that the patterns of kinase and cytokine activation differ. However, p38 regulates several anti-inflammatory pathways in addition to traditional proinflammatory mediators. It is possible that the beneficial effects are mitigated by the loss of these negative feedback loops.

The other two MAP kinases are also potential therapeutic targets. The ERK pathway, which regulates cell growth and some inflammatory mediators, can be blocked by inhibiting its upstream kinases MEK1 and MEK2. One clinical trial with a small molecule inhibitor saw minimal benefit, although the placebo response rate was high. Two of the three JNK isoforms (JNK1 and JNK2) regulate a variety of genes in inflammation including TNF and metalloproteinases. Using a JNK inhibitor, marked protection of bone destruction was observed in the adjuvant arthritis model, along with decreased synovial AP-1 activation and collagenase gene expression.¹⁵¹ No benefit was observed in the JNK1^{-/-} mice, and only modest cartilage protection was seen in the JNK2^{-/-} animals.

As an alternative to blocking MAP kinases themselves, upstream kinases might be targeted. MKK3 and MKK6, which regulate p38, are activated in the rheumatoid synovial intimal lining. MKK3 knockout and MKK6 knockout mice have markedly decreased joint inflammation in the passive K/BxN model.¹⁵² MKK4 and MKK7 are the main kinases that modulate JNK function and are also activated in the rheumatoid synovium. Only MKK7 is required for cytokine-stimulated JNK activation and MMP expression in cultured synoviocytes.¹⁵³ Going even further upstream is also possible, and targeting TAK1, which plays a role in NFκB and JNK activation, could have broader effects.

Janus Activated Kinases and the Signal Transducers and Activators of Transcription

The JAK proteins are key proteins that transduce signals from a wide variety of cytokine and growth factor receptors. Four JAKs have been identified (JAK1, JAK2, JAK3, and TYK1), and they can form heterodimers and homodimers. The specific JAK proteins responsible for individual cytokine responses are not fully elucidated, but some general guidelines are available. JAK3 provides the signaling for many T cell–derived cytokines, and mutations in this gene are responsible for severe immunodeficiency. JAK1/JAK2 is responsible for the IL-6 family and interferons. JAK2/JAK2 signals for growth factors such as erythropoietin. The distribution and expression levels for JAKs in RA are not well defined. However, all four genes are expressed in cultured FLS and immunohistochemistry studies localize JAK3, especially in sublining DCs.¹⁵⁴

The JAK proteins have become a focus of interest due to the efficacy demonstrated by a JAK inhibitor in RA clinical trials.¹⁵⁵ The benefit observed was similar to biologics, although issues related to adverse events and safety still need to be understood. The best isoform specificity also needs to be defined in order to maximize safety and efficacy. Because IL-6 signals through kinases such as JAK1, one should anticipate that this particular signaling molecule would be especially important for RA. On the other hand, a more T cell–directed approach for indications such as transplantation might focus more on JAK3 and could potentially have longer-term benefits in complex diseases of innate and adaptive immunity.

The JAK proteins phosphorylate the signal transducers and activators of transcription (STATs). The STATs can then translocate to the nuclei, where they can alter gene transcription. STATs have been implicated in the expression of many proinflammatory genes. IFNs signal through STAT1, IL-6 signals through STAT3, and IL-12 signals through STAT4.

Multiple STATs are expressed in rheumatoid synovium. STAT1 activation correlates with disease activity in RA (Figure 69-14), and a STAT1 decoy oligonucleotide suppresses antigen-induced arthritis in mice.¹⁵⁶ In addition, studies of rheumatoid tissue have an expression signature suggesting STAT1-regulated gene expression. STAT3, which is responsible for IL-6 signaling, has also been detected in cells from inflamed joints and can promote survival of cultured FLS. Synovial fluid from RA patients can activate STAT3 due to the presence of IL-6. STAT3 is also strongly phosphorylated in RA synovium, which is consistent with the role of IL-6 in RA and the efficacy of the IL-6 receptor antibody. Surprisingly, activation of the IL-4 pathway (STAT6) has also been demonstrated in RA tissues even though IL-4 expression is low.

Gene signature patterns using microarray technology have been evaluated in RA and correlated to histopathology. These studies can be difficult to interpret because of wide variations in the synovial cell populations, sampling error, and the statistical vagaries of managing large volumes of data. One study suggested that RA patients could be divided into a group with a STAT1 signature and the other with a signature reminiscent of tissue repair and remodeling.¹⁵⁷ With sufficient refinement, one could potentially

Figure 69-14 Phospho-STAT1 expression in rheumatoid arthritis synovium. Signal transducer and activator of transcription-1 (STAT1) is a transcription factor activated by the Janus kinases that regulates interferon responses. The figure shows expression of STAT1 in the synovial intimal lining using immunohistochemistry (**A**). **B** shows a synovial biopsy from the same patient after treatment with a traditional disease-modifying antirheumatic drug. Note that expression markedly decreased after therapy. (From Walker JG, Ahern MJ, Coleman M, et al: *Changes in synovial tissue Jak-STAT expression in rheumatoid arthritis in response to successful DMARD treatment*, *Ann Rheum Dis* 65:1558, 2006.)

identify subpopulations of patients that might respond to targeted therapies.

Interferon Regulation: IKK-Related Kinases and Interferon Regulatory Factor-3

Interferon signatures have been noted in several autoimmune diseases including RA. Type I interferons are expressed in RA synovium, especially by synoviocytes in the intimal lining. Regulation of IFN production and the IFN-response genes such as *RANTES*, *IP-10*, and *MCP-1* involves a pathway that runs parallel to the canonical NF κ B pathway and includes two IKK-related kinases, known as IKK ϵ and TANK binding kinase 1 (TBK1). Triggered when TLR3 is ligated by viral dsRNA, IKK ϵ and TBK1 phosphorylate the transcription factor interferon regulatory factor 3 (IRF3) and induce production of an array of genes that orchestrate this response including *RANTES* and IFN- β . IKK ϵ and its substrate IRF3 are expressed and highly activated in RA synovium. Using a combination of IKK ϵ ^{-/-} mice and genetic constructs that block endogenous IKK ϵ and TBK1 activity, the IKK-related kinases were shown to be a key regulator of

IFN- β , *RANTES*, and MMP expression in cultured FLS.¹⁵⁸ In contrast to DCs, where IRF7 is the primary IRF that regulates IFN responses, IRF3 is the pivotal factor that is responsible for the IFN signature.¹⁵⁹

Overexpression of some IRF3-driven genes, most notably IFN- β , could have a beneficial impact in inflammatory arthritis. Mice with collagen-induced arthritis injected with IFN- β or transduced fibroblasts expressing IFN- β have less severe disease compared with controls including decreased bone and cartilage destruction. A clinical trial of IFN- β in RA showed no benefit. An alternative approach might be to inhibit IKK-related kinases to block the chemokines associated with the IFN response and concomitantly treat with low levels of exogenous IFN- β .¹⁶⁰

Spleen Tyrosine Kinase and Other Signaling Pathways

Several other signaling molecules have been implicated in RA and are potential therapeutic targets. For example, spleen tyrosine kinase (Syk) is involved in immunoreceptor signaling in a variety of cell types. For example, Syk plays a critical role in Fc receptor signaling in macrophages and mast cells. It also participates in B cell activation after ligation of the B cell receptor. A small molecule Syk inhibitor has demonstrated efficacy in patients with RA, although significant benefit was not observed in individuals that did not respond to TNF blockers.¹⁶¹ c-Kit blockade has also been evaluated in an open-label study that provided a positive signal. PI3 kinases, especially the gamma and delta isoforms, are also attractive therapeutic targets due to their role in innate immunity and cell recruitment. There is no shortage of targets, and many others including upstream MAP kinase regulators, Ras, IL-1 associated kinases (IRAKs), sphingosine kinase-1 (SK-1), and Bruton's tyrosine kinase (BTK) will be evaluated in the future.

CELL SURVIVAL AND DEATH IN RHEUMATOID SYNOVIUM

KEY POINTS

Reactive oxygen and nitrogen in RA joints contribute to a toxic environment that can damage cells and increase inflammation.

Deficient apoptosis, or cell death, can contribute to the accumulation of cells in rheumatoid synovium.

Abnormalities of key regulatory genes such as the p53 tumor suppressor can enhance accumulation of cells in the joint.

Inducing apoptosis can potentially suppress synovial inflammation and joint destruction.

Studies defining the life cycle of cells have opened a new door to understanding the pathogenesis of neoplastic and inflammatory diseases. Although most investigators previously focused on cell proliferation as a mechanism of synovial hyperplasia, increasing attention has been paid to the other side of the equation (i.e., whether insufficient cell death could also contribute to this process). In this section, the role of oxidative damage, programmed cell death, and permanent changes in the genome are discussed because they can alter the natural history of RA.

Reactive Oxygen and Nitrogen

Oxidative stress in the joints of RA patients results from increased pressure in the synovial cavity, reduced capillary density, vascular changes, an increased metabolic rate of synovial tissue, and locally activated leukocytes. The generation of reactive oxygen species can also be facilitated by repetitive ischemia-reperfusion injury in the joint. Tissue injury releases iron and copper ions and heme proteins that are catalytic for free-radical reactions. Electron transport chains are also disrupted in the mitochondria and endoplasmic reticulum, leading to leakage of electrons to form superoxide.

Evidence for increased production of reactive oxygen species in RA patients includes elevated levels of lipid peroxidation products, degradation of hyaluronic acid by free radicals, decreased levels of ascorbic acid in serum and synovial fluid, and increased breath pentane excretion. Moreover, the levels of thioredoxin, a marker of oxidative stress, are significantly higher in synovial fluid from RA patients compared with other forms of arthritis. Peripheral blood lymphocyte DNA from RA patients contains significantly increased levels of the mutagenic 8-oxohydrodeoxyguanosine, which is a product of oxidative damage to DNA, pointing to the genotoxic effects of oxidative stress.

Nitric oxide (NO) production is also high in rheumatoid synovial tissue. Low levels of NO are constitutively produced by endothelial or neuronal synthases, and this is substantially increased by inducible NO synthase after stimulation by cytokines or bacterial products. The nitrite levels in synovial fluid are elevated in RA patients, indicating local NO production. In addition, the urinary nitrate-to-creatinine ratio is increased and inducible NO synthase is present in the synovium.

Apoptosis

Programmed cell death, or apoptosis, removes cells safely from living tissue and permits remodeling, or cell deletion without causing an inflammatory response. Apoptosis is a normal process that is tightly regulated and can be initiated by withdrawal of hormones and growth factors. It is evident in the elimination of autoreactive cells such as thymocytes in the thymus gland and the loss of cells after DNA damage or toxic exposure. It also plays a critical role in immune response by deleting activated T cells and terminating an inflammatory response by rapidly removing neutrophils.

Genes Regulating Apoptosis

The accumulation of cells in RA results from a balance of cell recruitment, cell egress, local proliferation, and local death. Any imbalance can potentially lead to synovial hyperplasia. T cell apoptosis in RA synovial effusions, for instance, is significantly less than lymphocytes from crystal-induced arthropathy. High expression of the antiapoptotic molecule Bcl-2 is found in lymphoid aggregates and protects synovial T cells from programmed cell death. Resistance to apoptosis *in vitro* increases if RA T cells are cocultured with FLS. The specific adhesion molecules involved are not defined, although the integrin-binding RGD motif

(arginine-glycine-asparagine) blocks the protective effects of synoviocytes.

Fas and its TNF superfamily counter-receptor Fas ligand (FasL) are potent regulators of cell death for many cell types including synovial T cells and synoviocytes. Fas is expressed by rheumatoid synovial fluid T cells, and the number of Fas⁺ cells in the peripheral blood of RA patients is greater than in healthy controls.¹⁶² Anti-Fas antibody, which cross-links Fas on cell surfaces, rapidly causes apoptosis in synovial fluid B and T lymphocytes in RA, although peripheral-blood T cells are more resistant. Another member of the TNF superfamily, TNF-related apoptosis-inducing ligand (TRAIL) binds to two receptors (DR4 or DR5) to induce caspase-dependent apoptosis. DR5 is expressed in RA FLS but not OA cells, and apoptosis can be induced by either TRAIL or agonistic anti-DR5 antibody.¹⁶³

Studies of apoptosis in RA synovial tissue show only a small number of apoptotic nuclei in the intimal lining and sublining.¹⁶⁴ Electron microscopic studies show rare cells that exhibit the typical findings of programmed cell death. Lymphoid aggregates containing high levels of Bcl-2 have few apoptotic cells. Macrophage apoptosis is also low because they express high levels of the caspase 8 inhibitor FLICE-like inhibitory protein (FLIP), which can inhibit Fas-mediated apoptosis.

The mechanisms for inducing apoptosis in FLS can involve several pathways including induction of JNK and AP-1 activation, inhibition of the kinase Akt, or suppression of NFκB. However, it is comparatively difficult to induce apoptosis in cultured synoviocytes. p53, which typically induces cell-cycle arrest and either DNA repair or apoptosis, is also expressed in the synovial lining and sublining. However, one of the main effectors of p53-mediated apoptosis, p53 upregulated modulator of apoptosis (PUMA), is only present in low concentrations in the synovium and cultured synoviocytes. Synoviocytes are resistant to p53-mediated apoptosis even when cells are forced to overexpress the protein using genetic methods.¹⁶⁵ Fas is constitutively expressed by cultured synoviocytes, and programmed cell death is initiated in a minority of cells when it is cross-linked by anti-Fas antibody. Synoviocyte apoptosis can be initiated by oxidative stress such as hydrogen peroxide or by exposure to nitric oxide.

The relative paucity of apoptosis in RA can also be partially explained by patterns of gene expression that favor cell survival. Sentrin-1, a ubiquitin-like protein, regulates the cell survival by modifying proteins involved in apoptosis. Sentrin-1 is expressed in RA synovium, especially at sites of cartilage invasion, and protects cells from Fas-mediated death. A second protein, phosphatase and tensine homolog on chromosome 10 (PTEN) was originally defined as a key factor that protects from tumorigenesis through antagonism of PI3K, Akt, and many other proliferative pathways. Underexpression of PTEN in RA has been described in rheumatoid synovial intimal lining, as well as cultured FLS.¹⁶⁶

Therapeutic Interventions That Increase Apoptosis. Fas-induced death has some clinical relevance and has been used successfully in murine collagen-induced arthritis using anti-Fas antibodies and adenovirus encoding for Fas ligand. Anti-Fas antibody also induces synovial cell death in RA synovial tissue explanted in SCID mice. In the SCID

mouse model using RA synovial explants, anti-DR5 antibody decreased cartilage erosion. Similarly, adenoviral transfer of TRAIL in a rabbit model of arthritis decreases synovial inflammation.¹⁶⁷ The importance of apoptosis as a regulator of inflammation was confirmed in murine collagen-induced arthritis, where genetic DR5 deficiency exacerbated the disease. Blocking FOXO30 in PMNs is also an effective method of deleting these inflammatory cells and suppressing inflammatory arthritis in mice.

The Bcl2 homology 3 (BH3) domain-only proteins are potent inducers of apoptosis. The challenge is how to get these proteins expressed in the target cell.¹⁶⁸ One of these, Bim, was engineered into a cell membrane permeable protein (TAT-Bim) and evaluated in the passive K/BxN model. The construct decreased arthritis severity in prophylactic and therapeutic treatment protocols and was associated with apoptosis of cells, mainly in the myeloid lineage. Therefore targeted cell death of individual lineages can potentially decrease inflammatory arthritis.

Other molecules that regulate apoptosis have also demonstrated potential utility in animal models. For instance, NFκB blockade in streptococcal cell-wall arthritis induces synovial apoptosis and suppresses arthritis. *p53* gene therapy in rabbit antigen-induced arthritis induces synovial apoptosis and decreases inflammation.¹⁶⁹ The pleiotropic activities of *p53* were demonstrated in collagen-induced arthritis because *p53*^{-/-} mice with the disease developed increased inflammation and greater joint destruction in association with decreased apoptosis. Joint damage was mediated by increased expression of collagenase genes in the knockout mice, most likely because *p53* directly suppresses MMP gene transcription.¹⁷⁰ However, *p53* knockout mice with passive models of arthritis have normal disease severity.¹⁷¹ This suggests that the protective effects of *p53* are partly due to effects on adaptive immunity.

Tumor Suppressor Genes

The *p53* tumor suppressor is a key regulator of DNA repair and cell replication. *p53* protein expression is significantly greater in the rheumatoid synovium compared with OA and normal tissue.¹⁷² Of interest, *p53* protein can also be detected in RA synovium from patients with very early RA. However, its expression is much lower in other inflammatory arthropathies such as reactive arthritis, which might reflect greater DNA damage and oxidative stress in RA.

Somatic mutations in the *p53* gene occur in RA synovium could contribute to the unusual phenotype of RA synovocytes and inadequate apoptosis in synovial tissue.¹⁷³ Transition mutations, which are characteristic of damage induced by reactive oxygen or nitric oxide, account for more than 80% of the base changes. Some of the mutant *p53* genes exhibit dominant negative characteristics and suppress the function of the wild-type allele. Microdissection studies identified mutant islands with oligoclonal expansion, and the loss of *p53* function in a region of RA synovium was associated with increased IL-6 gene expression in the same location. The data suggest that mutations do not cause RA but, instead, are the result of long-standing oxidative stress. The gene alterations can then potentially increase the aggressive nature of the synovium and alter the natural history of RA.

Abnormalities in other genes have also been reported in RA. For instance, synovial T cells in RA have an increased incidence of mutations in the *HPRT1* gene. Although not functionally important, these synovial T cells act as a marker for oxidative damage that occurs in the synovial milieu. Some of these abnormal lymphocytes can also be detected in the peripheral blood, suggesting that articular T cells can migrate out of the joint.

Microsatellite instability, which is marked by mutations in mononucleotide and dinucleotide repeat sequences in noncoding DNA, is also significantly greater in RA than OA synovial tissue. Occasional mutations in a coding region microsatellite in the *WISP-3* gene, which can regulate type II collagen and aggrecan expression, have been identified in RA synovium. However, similar mutations were observed in OA, suggesting that these are not specific. Mutations in mitochondrial genes have also been described in RA, most likely due to oxidative damage.

Evaluation of DNA mismatch repair (MMR) genes in rheumatoid synovium suggests that the balance of two genes that protect against mutations might contribute to the pattern of DNA damage in RA, with relatively high levels of MSH3 and low levels of MSH6 after reactive nitrogen stress.¹⁷⁴ The former repairs large insertions and deletions, whereas the latter repairs single-base abnormalities. Because most mutations detected in RA involve single bases, the changes in MMR enzyme levels favor these limited mutations rather than more substantial ones.

BLOOD VESSELS IN RHEUMATOID ARTHRITIS

KEY POINTS

Angiogenesis is a dynamic process in RA that provides nutrients to expanding synovium.

Angiogenic factors such as IL-8, FGF, and VEGF can enhance blood vessel proliferation in the synovium.

Microvascular endothelium in the synovium expresses adhesion molecules that guide circulating cells into the joint under the influence of chemoattractants.

Blood vessels play an active role in such inflammatory processes, not only as a means of selecting which cells should enter the tissue but also as a determinant of tissue growth and nutrition through the proliferation of new capillaries. Understanding the structure and function of the microvasculature provides insights into how a highly catabolic tissue such as the rheumatoid synovium can flourish.

Angiogenesis in Rheumatoid Arthritis: Feeding the Starved Synovium

The importance of luxurious new capillary growth early in the development of synovitis has been recognized for many years. The absolute number of blood vessels is increased in RA synovium (Figure 69-15), with a rich network of sublining capillaries and postcapillary venules in histologic sections stained with endothelium-specific antibodies. These blood vessels, however, are not necessarily normal, with a predominance of straight, branching morphology compared

Figure 69-15 Human rheumatoid synovial membrane stained with antibody to von Willebrand factor to delineate blood vessels. Virtually all of these blood vessels formed in response to angiogenic stimuli after the rheumatoid process had been initiated. (Courtesy Dr. Paul-Peter Tak.)

with tortuous vessels in psoriatic arthritis synovium. The blood vessels in the inflamed synovium were less mature, probably due to increased DNA damage and decreased recruitment of pericytes. Of interest, the immature vasculature is selectively depleted by TNF blockers in RA.¹⁷⁵

Hypoxia

The mass of tissue outstrips angiogenesis in RA as determined by the number of blood vessels per unit area and causes local tissue ischemia.¹⁷⁶ Synovial fluid oxygen tensions are remarkably low, lactate measurements are frequently high, and the pH can be as low as 6.8. The mean rheumatoid synovial fluid PO₂ in samples from rheumatoid knees is approximately 30 mm Hg and occasionally less than 15 mm Hg. Another cause of diminished blood flow is increased positive pressure exerted by synovial effusions within the joint, a process that obliterates capillary flow while producing ischemia-reperfusion injury in the joint. Altered vascular flow may not be the only cause of hypoxia in joints; oxygen consumption of the rheumatoid synovium is 20 times normal.

Hypoxia is a potent stimulus for angiogenesis, and many angiogenic factors are regulated by the hypoxia-sensing protein HIF-1 α . Low oxygen tension also leads to HIF-1 α -induced transcription of VEGF, a specific endothelial cell mitogen that is present in high concentrations in rheumatoid synovial fluid and tissue. Elevated serum concentrations in early disease correlate with subsequent radiographic progress. VEGF also stimulates expression of collagenase, which can degrade the extracellular matrix to make room for the advancing vasculature and pannus. VEGF expression is especially high in the synovial intimal lining, and the angiogenesis factor is also produced by cultured FLS that have been exposed to hypoxia and IL-1. HIF-1 α has other functions that regulate inflammation; selective deficiency in myeloid lineage cells suppresses inflammation in the passive K/BxN model of arthritis.¹⁷⁷

Angiogenic Factors

VEGF can bind to two receptors with tyrosine kinase domains: VEGF-R1/Flt-1 and VEGF-R2. VEGF-R1 regulates inflammatory responses in macrophages such as IL-6 and phagocytosis. VEGF-R1^{-/-} mice are resistant to arthritis in the HTLV1 pX model, which is marked by unregulated proliferation of synovial cells. Small-molecule VEGF-R inhibitors also suppress acute models of inflammation such as carrageenan paw edema and mouse collagen-induced arthritis. Therefore targeting this receptor with a small molecule might suppress the angiogenic and proinflammatory actions of VEGF.

In addition to the hypoxia-driven stimulus for blood vessel growth, the inflammatory cytokine milieu of the joint also encourages angiogenesis. Several proinflammatory factors expressed by the rheumatoid joint including IL-8, FGF, and TNF are angiogenic. Many of these cytokines further enhance angiogenesis by increasing expression of angiopoietins (Ang-1 and Ang-2) by synoviocytes, which can then bind to their tyrosine kinase receptor, Tie-1, on RA capillary endothelial cells. Additional angiogenesis factors derived from activated adhesion molecules on the surface of endothelial cells such as soluble E-selectin and soluble VCAM are released in RA synovium and contribute to vascular proliferation.¹⁷⁸ Limited quantities of some anti-angiogenic mediators that inhibit capillary proliferation such as platelet factor-4 and thrombospondin are also produced by the joint.

Vascular remodeling is an active process that involves the continuous creation and resorption of blood vessels. In RA, new capillaries that form under the influence of pro-angiogenic factors can be identified by the expression of integrins such as $\alpha_v\beta_3$. Endothelial proliferation is especially prominent in synovial tissue regions containing VEGF. Synovial blood vessel involution can also be detected as evidenced by apoptosis of the endothelium in other synovial locations. The ratio of proliferating and involuting blood vessels is significantly higher in RA than OA or normal synovium.

Targeting Angiogenesis

The importance of new blood-vessel formation in inflammatory arthritis was elegantly demonstrated in the collagen-induced arthritis model. The disease was markedly attenuated in animals pretreated with an angiostatic compound similar to fumagillin, which is derived from *Aspergillus*.¹⁷⁹ This compound is cytotoxic to proliferating, but not resting, endothelial cells. In addition, there was regression of established arthritis if treatment was initiated well into the course of the disease. Hence angiogenesis is essential for the establishment and progression of inflammatory arthritis because of the need for blood vessels to either recruit leukocytes or provide nutrients and oxygen to starved tissue.

Targeting HIF-1 α with a small molecule inhibitor that blocks nuclear translocation and VEGF induction was effective in adjuvant arthritis.¹⁸⁰ Other small molecule inhibitors of the VEGF-R1 with either antibodies or kinase inhibitors have been successfully tested in preclinical models of arthritis as well. One of these, vatalanib, decreased inflammatory knee arthritis in rabbits.

Several other antiangiogenesis approaches are effective in animal models of arthritis. For instance, thrombospondin 1 overexpression significantly decreased blood vessel density, inflammation, and joint destruction in rat collagen-induced arthritis. Direct intra-articular administration of a cyclic RGD peptide was used in a rabbit model to block $\alpha_v\beta_3$ integrin.¹⁸¹ As with RA synovium, $\alpha_v\beta_3$ is expressed by proliferating blood vessels in inflamed rabbit synovial tissue. The cyclic peptide decreased joint inflammation, increased endothelial cell apoptosis, and suppressed bone and cartilage destruction.

The ability of RGD to bind selectively to proliferating blood vessels was also used to home a proapoptotic agent to synovial neovasculature in murine collagen-induced arthritis.¹⁸² The cyclic RGD peptide was administered systemically and accumulated in inflamed synovium but not normal joints or other organs. Apoptosis was induced in synovial blood vessels and arthritis regressed. The potent angiogenesis inhibitor endostatin has been tested in the SCID mouse model, and it decreased synovial explant inflammatory cell infiltration and capillary density. Despite the compelling rationale for antiangiogenic therapy, an anti- α_v antibody showed minimal efficacy in a clinical trial, perhaps because other pathways are more important in the synovium.

Adhesion Molecule Regulation

Endothelial cells activated by cytokines and other mediators express adhesion molecules that bind to counter-receptors on mononuclear cells and neutrophils from the circulation and facilitate their recruitment from the blood (see Chapter 25). Several categories of vascular adhesion molecules exist. The selectins (E-, L-, and P-selectin) are a family of adhesion molecules whose primary ligands are carbohydrates, especially sialyl Lewis_x, and related oligosaccharides. A second family is integrins, which are heterodimers that include an α - and a β -chain. The counter-receptors depend on the specific combination of these chains and are frequently proteins in the immunoglobulin supergene family or extracellular matrix proteins. Several novel peptides have been described that selectively bind to the blood vessels of human synovial explants in SCID mice and have potential utility as inhibitors of cell adhesion, specifically to joint tissue.

Integrins and Ligands

As one might expect, adhesion molecule expression is increased in the RA synovium due to the rich cytokine milieu. Immunohistochemical techniques localize high levels of ICAM-1 to sublining macrophages, macrophage-like synovial lining cells, and fibroblasts compared with normal tissue.¹⁸³ Significant amounts are also present on the majority of vascular endothelial cells. Cultured FLS also constitutively express ICAM-1, which can be markedly increased by TNF, IL-1, and IFN- γ . ICAM-1 and the other ICAM family members can bind to cells expressing the β_2 integrins, especially neutrophils.

Adhesion of $\alpha_4\beta_1$ (VLA-4)-expressing mononuclear cells such as memory T cells or monocytes to cytokine-activated endothelial cells can be mediated by VCAM-1 or CS-1 fibronectin. A role for VLA-4 in arthritis has been suggested

by a number of experimental observations. In adjuvant arthritis in rats, anti- α_4 antibody decreases lymphocyte accumulation in the joint but not lymph nodes, suggesting that VLA-4 is more important in recruitment to inflamed sites than to noninflamed sites.¹⁸⁴ T lymphocytes isolated from the synovial fluid and synovial membrane of RA patients exhibit increased VLA-4-mediated adherence to VCAM-1, relative to autologous peripheral blood lymphocytes. These studies also suggest that leukocytes expressing functionally activated VLA-4 are selectively recruited to inflammatory sites in RA. Anti- α_4 antibody has potential utility in RA, but enthusiasm is mitigated by effects on host defense observed with natalizumab in multiple sclerosis.

Moderate amounts of VCAM-1 are expressed in RA synovial blood vessels. Surprisingly, the intimal lining is the location of the most intense staining with anti-VCAM-1 antibodies on histologic sections. Even normal synovial tissue expresses VCAM-1 in the lining, albeit less than in RA. Cultured FLS constitutively express small amounts of VCAM-1, and the level is increased by a variety of macrophage and T cell-derived cytokines. VCAM-1 also contributes to T cell adhesion to high endothelial venules in frozen sections of RA synovium.¹⁸⁵ The other VLA-4 counter-receptor, CS-1-containing forms of FN, is restricted to inflamed RA vascular endothelium and the synovial intimal lining.

The integrin $\alpha_4\beta_7$, which also binds to VCAM-1, is a specific adhesion molecule involved in lymphocyte homing to Peyer's patches. Most intraepithelial and lamina propria lymphocytes express $\alpha_4\beta_7$; this molecule is rarely identified in other lymphoid tissues. The expression of $\alpha_4\beta_7$ on peripheral blood lymphocytes from patients with RA is low (similar to normal individuals), but up to a quarter of synovial fluid lymphocytes, mostly CD8⁺ T lymphocytes, express this adhesion molecule and provide an interesting link between arthritis and the gut.¹⁸⁶

Selectins

E-selectin expression is also elevated in rheumatoid synovium, although the increase is less dramatic than for the integrins and their counter-receptors. This might be due, in part, to the kinetics of E-selectin expression on endothelial cells, which is transient after stimulation with cytokines.

Therapeutic Potential of Blocking Adhesion Molecules

The therapeutic potential for antiadhesion therapy has been studied in the SCID mouse model. Labeled human peripheral mononuclear cells were injected into engrafted mice, and migration into the tissue was examined.¹⁸⁷ If the mice were treated with TNF, ICAM-1 expression and trafficking into synovium were significantly increased. Anti-ICAM-1 antibody blocked leukocyte migration into the explant under these conditions. In another study, tonsil mononuclear cells also migrated into the RA synovial grafts in SCID mice. RA clinical trials using anti-ICAM-1 therapy have been reported using anti-ICAM-1 antibody or antisense ICAM-1 oligonucleotides, although minimal significant clinical benefit was observed. In addition, mice

lacking E- and P-selectin actually had accelerated disease in the collagen-induced arthritis model. This paradoxical result serves as a reminder of the complexity of the inflammatory process.¹⁸⁸

CARTILAGE AND BONE DESTRUCTION

KEY POINTS

Cartilage degradation and bone destruction in RA are mediated by distinct mechanisms and cell types.

Several classes of proteases including metalloproteinases, serine proteases, cathepsins, and aggrecanases are produced by intimal lining cells in RA, especially FLS.

Synovial lining cells, especially FLS, can invade and damage cartilage in RA.

Bone destruction is mediated by osteoclasts that are activated under the influence of RANKL and other cytokines produced by RA synovium.

Cartilage Destruction and the Pannus-Cartilage Junction

In RA, the cartilage is initially covered by a layer of tissue composed of mesenchymal cells. In the established lesion, macrophage-like and fibroblast-like cells penetrate into cartilage matrix (Figure 69-16). Invasive pannus is more commonly found in metatarsophalangeal joints, compared with hip and knee joints in which a layer of resting fibroblasts appeared to separate pannus from cartilage, perhaps explaining why erosions occur more often around small joints.

FLS from the intimal lining are major effectors of cartilage destruction in RA. They produce prodigious amount of proteases, bind to cartilage, and invade into the extracellular matrix. The pivotal role of synoviocytes in cartilage destruction was demonstrated in arthritis models using cadherin-11 blockade to disrupt the intimal lining.

Figure 69-16 Pannus-cartilage junction. The invasive front of pannus burrows into cartilage matrix in rheumatoid arthritis joints. The pannus is primarily composed of macrophages and mesenchymal cells. Immunostaining with anti-CD68 antibody shows the distribution of macrophages in the invasive tissue. (Courtesy Dr. Paul-Peter Tak.)

Cartilage destruction is markedly attenuated even though bone erosions progress.¹⁸⁹

Other cells in the joint, especially neutrophils and cells from the pannus that burrow directly into cartilage, could also be responsible for cartilage, whereas osteoclasts are responsible for bone erosions. More primitive mesenchymal cells isolated directly from the cartilage-pannus junction express phenotypic and functional features of both synoviocytes and chondrocytes and have also been described in the synovium.

Cartilage is destroyed in RA by both enzymatic and mechanical processes. The enzymes induced by factors such as IL-1, IL-17, TNF, phagocytosis of debris by synovial cells, and mechanical trauma degrade the matrix proteins. Early in synovitis, proteoglycans are depleted from the tissue, most likely due to the catabolic effect of cytokines such as IL-1 on chondrocytes with the production of MMPs and aggrecanases, and this leads to mechanical weakening of cartilage. As proteoglycans are depleted, cartilage loses elasticity and becomes susceptible to mechanical fragmentation and fibrillation. Eventually the tissue loses functional integrity concurrent with its dissolution by collagenases and stromelysins. Some of the MMPs responsible for this process are also derived from the chondrocytes themselves. Multiple MMPs, especially stromelysin and collagenase levels, are expressed in RA cartilage, and in situ hybridization studies confirm the presence of the mRNA within chondrocytes.¹⁹⁰ Hence the cartilage is under attack from a multitude of sources: It is bathed in protease-rich synovial fluid, is under extrinsic attack from the invasive pannus, is damaged from within by chondrocytes, and is fragmented by mechanical forces.

Enzymes released by PMNs in synovial fluid including neutrophil collagenase and multiple serine proteases also contribute to cartilage loss. Immune complexes containing RFs are embedded in the superficial layers of cartilage and can attract and activate neutrophils. Electron microscopic examinations of articular cartilage in RA reveal evidence of breakdown of collagen and proteoglycan due to superficial activity of joint fluid enzymes. In a rabbit model of arthritis in which IL-1 was injected directly into the joint, the degree of cartilage damage as measured by proteoglycan levels in synovial fluid correlated best with the stromelysin concentrations in synovial effusions (presumably derived from synoviocytes). Neutrophil depletion of animals did not interfere with subsequent destruction of extracellular matrix, suggesting that MMPs derived from the synovium are more important.

By and large, most animal studies indicate that IL-1 is a key regulator of matrix degradation in arthritis. Although TNF blockade has clear anti-inflammatory effects, chondroprotection is less prominent. The joint destruction observed in TNF-dependent models often requires IL-1. Recent data suggest that IL-17 and TLR ligands can also contribute to joint destruction directly or by synergizing with IL-1 and TNF.

The rate-limiting step in cartilage loss is the cleavage of collagen because proteoglycans are degraded soon after inflammation begins. MMPs, released into the extracellular space and active at neutral pH, are probably responsible for most of the effective proteolysis of articular-cartilage proteins, but other classes of enzymes may contribute to joint

destruction. Enzymes such as cathepsins B, D, G, K, L, and H may play a role within and outside cells in degrading noncollagenous matrix proteins. Serine proteinases (e.g., elastase and plasmin) and aggrecanases are doubtless involved as well.

Proteases: Mediators of Joint Destruction

Matrix Metalloproteinases

The MMPs are a family of enzymes that participate in extracellular-matrix degradation and remodeling (see Chapter 8). They are usually secreted as inactive proenzymes, and their proteolytic activity requires limited cleavage or denaturation to reveal a zinc cation at the core. Their activation can be mediated by other proteases including trypsin, plasmin, or tryptase. The substrates for MMPs are varied but quite specific for individual members of the family. Collagenases degrade native collagen types I, II, III, VII, and X, whereas gelatinases are able to degrade denatured or cleaved collagen. Stromelysins have broader specificity and can digest proteoglycans in addition to proteins. They also process procollagenase to the active form, thereby serving as a positive-feedback signal for matrix destruction. Some MMPs such as TNF convertase (TACE) are responsible for the processing and release of cytokines from the cell surface. Many different families of proteinases are found in the joint (Table 69-6), but the MMPs are thought to play a pivotal role in joint destruction.

Regulation of MMP Production. The cytokine milieu has the capacity to induce the biosynthesis of MMPs by synovial cells and alter the balance between extracellular matrix production and degradation. IL-1 and TNF, in particular, induce MMP gene expression by many cells, especially FLS and chondrocytes. The two cytokines are additive or synergistic when used in combination. Many other cytokines and TLR ligands implicated in rheumatoid synovitis can also induce MMP expression including IL-17, LIF, LPS, and peptidoglycans.

MMP induction is mediated by both an increase in gene transcription and mRNA stabilization. Culture medium from rheumatoid synovium stimulates cartilage degradation *in vitro*, and this is mainly due to IL-1. IL-6 does not induce MMP production by synovial cells but instead increases the production of TIMP-1, a naturally occurring inhibitor of

MMPs. TGF- β inhibits collagenase synthesis and enhances the production of TIMP by fibroblasts and chondrocytes. TGF- β also increases collagen production, shifting the balance from destruction to matrix repair.

Although multiple upstream regulatory sequences are involved in MMP gene transcription, the dominant element in the promoter is AP-1. Other regulatory sites such as an NF κ B-like region can also contribute to collagenase expression. AP-1 activity is markedly increased in FLS by proinflammatory cytokines, and its transcriptional activity is mediated by increased expression of components such as c-Jun. The MAP kinases are especially important for this activity, and JNK is the most efficient upstream activator. Glucocorticoids markedly inhibit MMP gene expression by blocking AP-1.

Collagenases and stromelysins have the capacity to degrade virtually all the important structural proteins in the extracellular tissues within joints. Collagenase-1 (MMP-1) cleaves through the triple-helical collagen molecule at a single glycine-isoleucine bond approximately three-quarters of the distance from the NH₂-terminus. This enzyme degrades only the interstitial helical collagens (e.g., types I, II, III, and X). It has little or no activity against types IV, V, and IX and other nonhelical collagens or denatured collagen; the degradation of the latter is primarily accomplished by the gelatinases. MMP-1, however, is a relatively inefficient enzyme, whereas collagenase-3 (MMP-13) has more favorable kinetics. Neutrophil collagenase, or MMP-8, is constitutively stored in neutrophil granules and is released into the milieu after degranulation. Of note, rodents lack the collagenase-1 gene, whereas the collagenase-3 gene is preserved. This is especially important to note when evaluating effects of MMP inhibitors in animal models.

MMP Expression in Synovium. The collagenase-1 and collagenase-3 genes are produced by RA synovial tissue, and the latter is highly expressed by chondrocytes in cartilage. *In situ* hybridization studies show that the primary location of collagenase-1 gene expression in the synovium, like many other MMPs, is the intimal lining, especially in fibroblast-like cells.¹⁹¹ Subchondral bone is another region in which proteinase expression occurs in RA and could participate in bone resorption. Increased MMP gene expression is an early feature of RA and occurs during the first few weeks of clinically active disease. High expression of collagenase-1, as well as gelatinases such as MMP-2, early in disease correlates with rapidly progressive erosions. Similarly, increased blood levels of the proenzymes are also associated with more severe disease.

Stromelysin-1 (MMP-3) and the other members of the stromelysin family have no activity against most native collagens but effectively degrade type IV collagen, fibronectin, laminin, proteoglycan core protein, and type IX collagen. Stromelysin removes the NH₂-terminal propeptides from type I procollagen and is integrally involved in the activation of procollagenase. Like collagenase, stromelysin gene expression occurs mainly in the synovial intimal lining (Figure 69-17). Despite the putative importance of this enzyme in matrix destruction, stromelysin knockout mice are susceptible to collagen-induced arthritis and develop as much joint destruction as mice with functional stromelysin.¹⁹² This observation led to decreased interest in stromelysin inhibitors to treat diseases such as RA.

Table 69-6 Key Proteases and Inhibitors in Rheumatoid Arthritis Synovium

Protease	Inhibitor
Metalloproteinases	TIMP family; α_2 -macroglobulin

Cathepsin K	

SERPINs, serine protease inhibitors; TIMP, tissue inhibitor of metalloproteinases.

Figure 69-17 Localization of stromelysin, tissue inhibitor of metalloproteinases-1 (TIMP-1), and actin mRNA in rheumatoid arthritis (RA) synovial tissue by in situ hybridization. Stromelysin is mainly expressed in the synovial intimal lining, presumably by cytokine-stimulated type B synoviocytes. Bright field and dark field views are shown. (Courtesy D. Boyle.)

MMP inhibitors are effective in animal models of rheumatoid arthritis and can suppress bone destruction, as well as the inflammatory synovitis. In models of osteoarthritis, deletion of MMP genes such as stromelysin do not necessarily improve outcomes. Clinical trials in RA using nonselective inhibitors have had minimal success and significant side effects, possibly related to decreased matrix turnover. Inhibitors of TACE (which can also block other MMPs) actually appear to increase disease activity in RA, perhaps due to increased levels of membrane-bound TNF. One of the most consistent side effects experienced by patients treated with MMP inhibitors is increased joint stiffness thought to result from deposition of fibrous tissue without sufficient protease activity to permit removal of matrix proteins. This observation has been replicated in rats, which provides an opportunity to determine if highly selective MMP inhibitors will have a better risk-benefit ratio.

Cysteine Proteases: The Cathepsins

Cathepsins are an extensive family of cysteine proteases that have broad proteolytic activity including activity on types II, IX, and XI collagen and proteoglycans. Like MMPs, the cathepsins are regulated by cytokines and by proto-oncogenes such as Ras. IL-1 and TNF induce cathepsin L expression in cultured FLS.¹⁹³ In situ hybridization studies demonstrate expression of cathepsin B and L in RA synovium, especially at sites of erosion. A ribozyme that cleaves cathepsin L decreases FLS invasion and cartilage destruction in the SCID mouse model with implanted cultured synoviocytes.

Cathepsin K has been implicated in bone resorption by osteoclasts. This protease is unique among the cathepsins because it can degrade native type I collagen. It is expressed in RA synovial tissue by both macrophages and fibroblasts

and is present in significantly higher concentrations than in OA.¹⁹⁴ Serum levels of cathepsin K correlate with the extent of radiographic damage. A potential role of cathepsins as mediators of bone destruction in arthritis was confirmed in studies in which a cysteine protease inhibitor significantly decreased joint damage in the rat adjuvant arthritis model. In the TNF-transgenic mouse model, lack of the cathepsin K deficiency decreased, but did not eliminate, bone erosions.¹⁹⁵

Aggrecanases

Aggrecan is a major proteoglycan component of articular cartilage. Because of its large size and negative charge, it contains a considerable amount of water, which increases compressibility. Two proteolytic sites are available on aggrecan in its globular domain. One site is susceptible to MMP cleavage, whereas the other, located 32 amino acids toward the C-terminus, is the site for cleavage by a family of enzymes known as aggrecanases. The two sites can be identified in tissues using monoclonal antibodies after cleavage when specific neoepitopes are revealed.

Normal cartilage contains a surprising amount of aggrecanase neoepitope, suggesting continuous matrix turnover. The level of aggrecanase cleavage product increases with age. Two aggrecanase genes, aggrecanase-1 and aggrecanase-2, have been cloned and are members of the “a disintegrin and metalloproteinase with thrombospondin motif” (ADAMTS) family of proteins (ADAMTS-4 and ADAMTS-5, respectively). They are expressed in OA and RA cartilage, and their proteolytic activity can be detected in synovial fluids. Especially high levels of the neoepitope are present in arthritic cartilage.¹⁹⁶ IL-1 increases aggrecanase expression in cartilage explants, as well as cultures of chondrocytes. Aggrecanase-1 and aggrecanase-2 are

constitutively expressed by RA and OA FLS and synovial tissues.¹⁹⁷ Aggrecanase-1 is induced in synoviocytes by cytokines, especially TGF- β , whereas aggrecanase-2 expression remains constant despite TGF- β or IL-1 stimulation. Genetic deletion of aggrecanase-1 has no effect on a murine osteoarthritis model. However, loss of aggrecanase-2 prevents degenerative changes.¹⁹⁸

Inhibitors of Protease Activity

α_2 -Macroglobulin (α_2 M) accounts for more than 95% of collagenase inhibitory capacity in serum. The mechanism of inhibition by α_2 M involves hydrolysis by the proteinase of a susceptible region in one of the four polypeptide chains of α_2 M (sometimes called the “bait”), with subsequent trapping of the proteins within the interstices of the α_2 M. Ultimately, the protease is covalently linked to a portion of the α_2 M molecule. The serine protease inhibitors (SERPINs) are also abundant in synovial effusions and plasma and can serve a dual purpose of directly blocking serine protease function and indirectly decreasing MMP activity by preventing serine proteases from activating MMP proenzymes. One SERPIN, α_1 -antitrypsin, has been well characterized in synovial fluid and is frequently inactivated after oxidation by reactive oxygen species.

A family of proteins that specifically block MMP activity, called TIMPs, has been cloned and characterized. The TIMP proteins block proteinase activity by binding directly to MMPs in a 1:1 molar ratio. TIMP generally binds only to the active enzyme, although exceptions such as TIMP-2 can interact with a progelatinase (MMP-2). The inhibitors bind to MMPs with extremely high avidity. Even though the interaction does not result in new covalent bonds, it is essentially irreversible.

TIMP proteins are present in RA synovial fluid in excess. It is, in fact, difficult to detect free active collagenase and stromelysin because they are usually complexed with the inhibitors. The majority of MMP, however, is in the proenzyme form. Immunohistochemical and in situ hybridization studies have localized the TIMPs in hyperplastic synovial lining cells in rheumatoid synovium, but not in the cells of normal synovium. TIMP gene expression is not significantly altered by IL-1 or TNF but is increased by IL-6, oncostatin M, and TGF- β . TIMP-3 knockout mice have significantly more synovial inflammation and TNF production in antigen-induced arthritis, perhaps because it is not available to inhibit TACE. Similarly, TIMP-1 or TIMP-3 gene transfer limits rheumatoid FLS invasion into cartilage in an SCID mouse model. The function of these genes can extend beyond protease inhibition and include a number of paracrine functions, as well as induction of apoptosis when expressed intracellularly in cultured synoviocytes.

Given the important role of MMPs in tissue destruction, the relative balance between MMPs and TIMPs ultimately determines the fate of the extracellular matrix. The ratio in RA, with its more destructive potential, favors degradation, whereas OA has a lower MMP-to-TIMP ratio. The levels of TIMP gene expression are similar in the two diseases and may well be maximal. The higher ratio in RA results from increased MMP production. This balance between protease and inhibitor can be modified in vivo with drug therapy. For instance, intra-articular corticosteroid injections markedly

decrease synovial collagenase, stromelysin, and TIMP gene expression. In contrast, chronic low-dose methotrexate therapy specifically decreases collagenase but not TIMP-1 mRNA.¹⁹⁹ Suppressed collagenase gene expression suggests that a low collagenase-to-TIMP ratio is one mechanism of decreased tissue destruction observed in patients treated with methotrexate.

Regulation of Bone Destruction

Osteoclasts are the major cells responsible for bone degradation. RANKL, which was originally described for its role in T cell–dendritic cell interactions, as well as lymphocyte and lymph node development, is perhaps the single most important factor that modulates bone resorption. Osteoclast development is complex and involves the differentiation of monocytes under the influence of cytokines such as M-CSF in combination with RANKL. Subsequent osteoclast activation can involve several pathways, most of which also depend on the presence of RANKL. Its receptor, known as RANK, is expressed by the osteoclast precursors. RANKL is produced by many cell types including activated T cells and FLS.

Abundant evidence implicates this powerful mechanism in bone destruction caused by inflammatory arthritis. For instance, administration of OPG, a RANKL decoy receptor, to rats with adjuvant arthritis inhibits bone destruction but has almost no effect on inflammation or clinical signs of arthritis.²⁰⁰ RANKL^{−/−} mice are also protected from bone erosions in the passive K/BxN model of arthritis, although cartilage destruction still occurs. Animal models of arthritis point to IL-17 as a mediator of osteoclast generation. Genetic deficiency of IL-17 or anti-IL-17 antibodies have remarkable bone-sparing effects in these experiments.

RANK, RANKL, and OPG (as well as M-CSF and IL-17) have been detected in the synovium and synovial fluid of patients with RA. The ratio of RANKL to OPG is significantly higher in RA synovial effusions than in either OA or gout, which is consistent with the more destructive nature of RA. Osteoclasts expressing tartrate-resistant acid phosphatase (TRAP), capable of forming resorption lacunae, can be generated from cultured RA synovial cells (Figure 69-18). This activity is blocked by the addition of exogenous OPG. RA synoviocytes and synovial membrane T cells that display RANKL can also induce differentiation of osteoclasts from peripheral blood cells.²⁰¹

The functional relevance of the RANK-RANKL system was confirmed in RA studies in which an anti-RANKL antibody denosumab decreased bone erosions. As predicted from animal model studies, the antibody had no effect on inflammation or clinical signs of synovitis.²⁰²

A second system that regulates bone remodeling involves the Wntless (Wnt) proteins. Several members of this family bind to receptors that regulate osteoblast differentiation through effects on β -catenin. Wnt signaling is modulated by many other proteins, most notably the Dickkopf (DKK) family. DKK-1 in particular blocks binding of Wnts to its receptors. In TNF-transgenic mice with arthritis, bone erosions are blocked by inhibiting either TNF or DKK-1. With the latter, proliferative bone lesions such as osteophytes formed instead.²⁰³ Therefore DKK-1 is a master switch that determines the fate of bone in inflammatory

Figure 69-18 Tartrate resistant acid phosphatase–positive osteoclasts are shown invading bone in rheumatoid arthritis (see arrows for examples). This process is regulated by RANKL in the presence of other cytokines such as macrophage colony-stimulating factor and tumor necrosis factor. (Courtesy Dr. Steven Goldring, Dr. Ellen Gravallese, and Dr. Allison Pettit.)

lesions. When present, bone destruction is favored; when absent, bone formation occurs.

Tissue Repair

Extracellular matrix turnover in RA has been likened to wound healing due to the critical role of collagen production, proteases, and protease inhibitors. Remodeling the matrix by removing damaged proteins is a key element in early repair. Subsequently, the balance shifts to protease inhibition, production of cytokine inhibitors, removal of inflammatory cells through apoptosis, and release of anti-inflammatory eicosanoids such as lipoxins to suppress inflammation. Neutralization of oxidants via glutathione reductase or superoxide dismutase further limits tissue damage.

This process then permits either a return to normal architecture or scar formation. TGF- β , in particular, appears to play a key role in that it increases collagen deposition, suppresses MMP expression, and enhances production of the TIMPs. Although TGF- β levels in the joint are substantial, they are not sufficient to overcome the impressive array of MMPs expressed in synovitis. The repair process is insufficient in RA, perhaps because of persistent T cell activation or autonomous activation of other cell lineages. However, strategies to shift from tissue damage by enhancing endogenous mechanisms might not only suppress symptoms but also enhance appropriate remodeling of the matrix to restore homeostasis.

Because the invasive rheumatoid synovium exhibits some properties similar to neoplastic diseases, the possibility that the tissue contains immature cells or embryonic genes that regulate repair has been explored. The embryonic growth factors from the wingless (wnt) and frizzled (fz) gene families have been demonstrated in RA synovium. Normally, these proteins participate in bone marrow progenitor differentiation and limb bud mesenchyme. Wnt5a and Fz5, in particular, are markedly elevated in RA tissues

and cultured synoviocytes. When normal fibroblasts are transfected with the WNT5A gene, cytokine expression such as IL-6 increases significantly. Antisense WNT5A and dominant negative WNT5A vectors diminish cytokine expression by synoviocytes.²⁰⁴

These data raise the possibility that immature mesenchymal cells populate the synovium in RA, either as a primary event or as a repair mechanism. Similar primitive mesenchymal cells circulate in the peripheral blood of RA and normal individuals, and in collagen-induced arthritis they infiltrate the synovium before clinically apparent synovial inflammation.

Restoring homeostasis and tissue repair in RA is therefore a complex process that involves the ingress or dedifferentiation of mesenchymal cells that can remodel the matrix. In addition to TGF- β , the function of these cells is modulated by the bone morphogenic proteins (BMPs). The BMPs are members of the TGF- β superfamily and, like TGF- β , signal through the Smad pathway. Several members including BMP-2 and BMP-7 are expressed in the joint and facilitate repair, although inappropriate release can also enhance joint damage or lead to ankylosis or enthesophyte formation.²⁰⁵ BMP function is also regulated by a family of inhibitors such as Noggin, which can surprisingly limit cartilage damage when overexpressed in murine antigen-induced arthritis. Modulating the relative balance and timing of BMP expression could ultimately be used to either modify the destructive influence of synovitis or regenerate damaged tissues.

SUMMARY

The etiology and pathogenesis of RA remains a complex problem, although the level of understanding has progressed considerably in recent years. Both T cell–dependent and T cell–independent processes contribute to disease initiation and perpetuation. Moreover, disease mechanisms might differ at various stages of the process. These hypotheses have unveiled many novel therapeutic targets and interventions that might lead to significant clinical benefit. Such was the case with the TNF inhibitors, B cell depletion, T cell costimulation, and most recently IL-6 inhibition, which have joined the pharmacopoeia for the treatment of RA. Early observations that defined the cytokine profile in arthritis and that delineated the biology of macrophage cytokines led to this breakthrough. Similarly, it is possible that understanding of apoptotic pathways, abnormalities in tumor-suppressor genes, the function of the susceptibility genes, signaling pathways, B cell function, or T cell differentiation will lead to new therapies.

Clinical Features of Rheumatoid Arthritis

SUSAN E. SWEENEY •
EDWARD D. HARRIS, JR. •
GARY S. FIRESTEIN

KEY POINTS

Rheumatoid arthritis is a symmetric inflammatory polyarticular arthritis that mainly affects the small joints of the hands and feet.

Larger joints can be involved, usually later and in a symmetric fashion.

Cartilage destruction and bone erosions are common, especially in rheumatoid factor–positive or anticitrullinated protein antibody–positive patients.

Uncontrolled synovitis can lead to severe deformity, loss of function, and increased mortality due to accelerated atherosclerosis.

Early therapy with aggressive treatment goals improves long-term outcomes in rheumatoid arthritis.

Systemic manifestations include rheumatoid nodules, pulmonary disease, vasculitis, serositis, and eye disease.

EPIDEMIOLOGY AND THE BURDEN OF DISEASE

The prevalence of rheumatoid arthritis (RA) in most populations is around 1% in most populations, with an incidence in women twice that in men. This number was based on many studies of population samples,¹⁻³ which varied among the surveys from 0.3% to 1.5%. The prevalence of RA in some populations might be changing, however, as suggested by more recent data on incidence rates in different decades. The incidence of RA in Rochester, Minnesota, decreased by 50% between 1950 and 1974. Differences between incidence and prevalence are enhanced by the realization that as the population ages, the prevalence of RA may increase or stay the same, regardless of short term trends in incidence simply because individuals with RA are living longer.

The incidence of RA increases during adulthood, except among men in their 40s through 60s. In Olmsted County, Minnesota, the increased incidence with increasing age continues until age 85, after which the incidence declines.⁴ In a 10-year extension of this study, the age-adjusted and sex-adjusted incidence per 100,000 population decreased from 62 in the decade 1955 to 1964 to 32.7 in the decade 1985 to 1994.⁵ The decrease was more prominent in women than in men, and the average age at onset of the disease shifted upward. Perhaps more intriguing were cyclic patterns of incidence within decades, suggesting the influence of environmental factors. One explanation for the decline in incidence and the shift toward older age at onset is a birth cohort effect, the greatest impact of which is seen early

in life.⁶ A recent update from the Olmsted County, Minnesota, cohort of RA patients from 1955-2007 examined trends in the incidence and prevalence of RA from 1995-2007. During the more recent time period, the incidence of RA in women, but not in men, increased moderately.⁷ Causes for this trend reversal in women were not determined but might involve environmental factors. Current incidence rates using this same population-based study of Minnesota patients revealed that the lifetime risk of RA among U.S. adults is 3.6% for women and 1.7% for men.⁸

Throughout the world, pockets of ethnic groups have a much higher incidence of RA. Native Americans constitute one of these groups. In one geographic area between 1986 and 1994, non-Native American populations had an RA prevalence of 1.1% to 0.9%, whereas the prevalence among Algonquian Indians in the same region ranged from 2% to 2.1%, and disease onset was seen 12 years earlier in the Native American population. Among Pima Indians, who bear a very high incidence of RA, a decline in incidence has been correlated with a decrease in seropositivity for rheumatoid factor (RF). The highest likelihood of seropositivity was noted in Pima Indians born at the turn of the 20th century, and seropositivity has decreased ever since that time. This provides additional supportive evidence for a birth cohort effect.⁹

Although newer, more effective therapy for rheumatoid patients has led to reduced morbidity and disability from the disease, dollar costs for RA, which recently surpassed the cost per patient for diabetes, are still substantial. In a panel of individuals with RA in San Francisco followed for 15 years, medical care costs for RA averaged \$5,919 per year, and additional costs of \$2,582 were incurred for medical but non-RA reasons.¹⁰ More than half of these costs were generated by hospitalization, with some patients bearing costs greater than \$85,000/year while their function declined. In another cohort of 4258 patients with RA followed for 17,085 patient-years, lifetime direct medical care costs were estimated to be \$93,296.¹¹

RISK FACTORS

A predisposition to RA appears to be multifactorial based on the following: (1) Relatively few identical twins have RA (about 15%), even though concordance for the disease is much more likely in twins than in the normal population; (2) despite the powerful influence of the “shared epitope” on HLA-DRB chains in predisposing to the severity of disease, this susceptibility allele is not a risk factor in certain population studies; and (3) the combination of many gene

polymorphisms confers a modestly increased risk for disease. A reasonable hypothesis is that the genetic predisposition to RA involves a propensity to autoimmune responses, but that repeated exposure to environmental agents is ultimately responsible for tipping the balance from subclinical autoimmunity to diseases such as RA. Many of the risk factors for RA are discussed in Chapter 69, especially genetic associations, environmental exposures, and the role of autoantibodies.

CLINICAL PRESENTATIONS OF EARLY RHEUMATOID ARTHRITIS

In the Northern hemisphere, the onset of RA is more frequent in winter than in summer. In several series, onset of RA from October to March in the Northern hemisphere was found to be twice as frequent as in the other 6 months.¹² The appearance of RF or anticitrullinated protein antibodies (ACPAs), also referred to as anticyclic citrullinated protein antibodies (anti-CCPs), often precedes symptoms of arthritis in patients. Approximately half of patients with RA have specific serologic abnormalities several years before the onset of symptoms. A finding of an elevated serum level of immunoglobulin (Ig)M-RF or anti-CCP in a healthy person correlates with increased risk of developing RA.¹³ This is especially important in light of the new criteria for RA classification in early RA because symptoms can be minimal for some of those who meet the criteria for diagnosis (see later).

Patterns of Onset

Insidious Onset

RA has an insidious, slow onset over weeks to months in 55% to 65% of cases.¹⁴ The initial symptoms may be systemic or articular. In some people, fatigue, malaise, swollen hands, and diffuse musculoskeletal pain may be the first nonspecific symptoms, with joints becoming involved later. Involvement of tendon sheaths early in the process can focus attention on periarticular structures. In retrospect, the patient often can identify one joint that was involved first, quickly followed by the others. Asymmetric initial presentations (often with increased symmetry developing later in the course of disease) are common. The reason for the symmetry of joint involvement compared with other forms of arthritis, such as the seronegative spondyloarthropathies, is unknown.

Morning stiffness is a cardinal sign of inflammatory arthritis that can appear even before pain and may be related to the accumulation of edema fluid within inflamed tissues during sleep. Morning stiffness dissipates as edema and products of inflammation are absorbed by lymphatics and venules and returned to the circulation by motion accompanying the use of muscles and joints. To be specific for joint inflammation, morning stiffness (e.g., “difficulty moving around”) should persist for at least 30 to 45 minutes before disappearing. A similar “gel” phenomenon can occur if a person is inactive during the day.

It is rare for symptoms to remit completely in one set of joints while developing in another. This quality of arthritis

sets RA apart from rheumatic fever or palindromic rheumatism, in which a true migratory pattern of arthritis is common. A subtle, early change in RA is the development of muscle atrophy around affected joints. Muscle efficiency and strength become diminished. As a result, weakness develops that can be out of proportion to pain. Opening doors, climbing stairs, and doing repetitive work rapidly become more demanding. A low-grade fever without chills is rarely present. Depression and anxiety can accentuate symptoms. A small but significant weight loss is common and reflects the catabolic effects of cytokines and associated anorexia.

Acute or Intermediate Onset

Among patients with RA, 8% to 15% have an acute onset of symptoms that peak within a few days. Rarely, a patient can pinpoint the onset of symptoms to a specific time or activity. Symptoms mount, with pain developing in other joints, often in a less symmetric pattern than in patients who have an insidious onset. Acute-onset RA is difficult to diagnose, and sepsis or vasculitis should be ruled out. Fever, suggesting an infectious process, can rarely be a prominent sign. An intermediate type of onset, in which symptoms develop over days or weeks, occurs in 15% to 20% of patients. Systemic complaints are more noticeable than in the insidious type of onset.

Joint Involvement

The joints most commonly involved first in RA are the metacarpophalangeal (MCP) joints, the proximal interphalangeal (PIP) joints, the metatarsophalangeal joints, and the wrists (Table 70-1).¹⁵ Larger joints generally become symptomatic after small joints. Synovitis in large joints is likely to remain asymptomatic for a longer time than in smaller ones, and a biopsy specimen of an asymptomatic knee often shows histologic evidence of synovitis.¹⁶ One anatomic study correlated the area, in square centimeters, of synovial membrane with that of hyaline cartilage in each joint. Joints with the highest ratio of synovium to articular

Table 70-1 Distribution of Joints Involved in Attacks Based on Cumulative Experience with 227 Patients

Joint Involvement	% Patients (Mean)	% Patients (Range)
MCP, PIP	91	74-100
Wrists	78	54-82
Knees	64	41-94
Shoulders	65	33-75
Ankles	50	10-67
Feet	43	15-73
Elbows	38	13-60
Hips	17	0-40
Temporomandibular	8	0-28
Spine	4	0-11
Sternoclavicular	2	0-6
Peri-articular sites	27	20-29

MCP, metacarpophalangeal; PIP, proximal interphalangeal.

cartilage correlated positively with those most frequently involved in the disease (see Table 70-1).¹⁷

Early Synovitis: Which Patients Develop Rheumatoid Arthritis?

Distinguishing early RA from other inflammatory arthropathies can be challenging. In its earliest stages, RA might involve only a few joints and may not show the typical symmetric distribution. What diagnostic clues can be used to determine who will progress to classic RA, and who will develop an alternative inflammatory arthritis such as one of the spondyloarthropathies or have a spontaneous remission? The implications for disease management are obvious because early treatment potentially could limit or prevent joint damage and possibly permit long-term remission or even cure. Because 30% to 40% of patients with early inflammatory synovitis have spontaneous remission, accurate identification of patients with RA is essential to avoid undertreatment and overtreatment.

Some of these questions have been addressed by the Leiden Early Arthritis Clinic, which evaluates patients with symptoms of less than 2 years' duration (most patients have symptoms for less than 6 months). In this cohort, only about 20% of patients met criteria for RA when initially evaluated by a rheumatologist.¹⁸ One-third of patients defied categorization and were considered to have "undifferentiated arthritis." When this group of patients was followed for 1 year, 27% ultimately developed RA, and 40% remained undifferentiated. Clinical features that were more commonly seen among patients who developed RA included greater numbers of joints involved (mean of seven joints vs. four joints), longer duration of morning stiffness (90 minutes vs. 60 minutes), and the presence of autoantibodies. These features were insufficient individually to permit early diagnosis of RA, although a composite scoring system has been proposed.¹⁹ The predictive value of this system approaches 90%.

Additional studies from the Leiden Early Arthritis Clinic show that assessment and management of patients with symptoms of less than 12 weeks' duration by a rheumatologist was associated with decreased joint destruction and increased likelihood of disease-modifying antirheumatic drug (DMARD)-free remission.²⁰ Treatment of early inflammatory synovitis with methotrexate therapy delays progression to RA, but disease ultimately progresses to RA if the medication is discontinued²¹ (see Chapter 42).

Among predictive features most likely to be useful in patients, serum autoantibodies might be the most

important. ACPAs, in particular, are strongly associated with the evolution of undifferentiated arthritis into RA and progression to erosive disease. In addition, the diversity of citrullinated peptides recognized by ACPAs increased during the period preceding onset of disease in patients who progressed to RA, suggesting that epitope spreading plays a role in the evolution of disease.²² Other autoantibodies have also been used in a diagnostic algorithm for patients with very early synovitis (symptoms of <3 months' duration), including RFs, anticitrullinated protein, and anti-RA33.²³ Through stepwise analysis of each antibody, RA could be diagnosed in 72% of patients and confirmed by subsequent clinical course and development of RA.

Other Patterns of Disease Onset or Variants of Disease

Palindromic Pattern

Palindromic rheumatism was described by Hench and Rosenberg in 1942. Pain usually begins with pain in one joint or in periarticular tissues; symptoms worsen for several hours to a few days and are associated with swelling and erythema. Then, in reverse sequence, symptoms resolve, leaving no residua. Table 70-2 lists joints involved in a series of 227 patients. An intercritical period, similar to that of gout, is asymptomatic. Half of patients with palindromic rheumatism go on to develop RA, particularly those with HLA-DR4. In a compilation of patients from nine series, only 15% became asymptomatic after at least 5 years with a palindromic syndrome (see Table 70-2).²⁴ In the remainder, multiple joints became involved, swelling did not subside completely between attacks, and tests for RF became positive. Neither the characteristics of joint fluid nor the pathologic findings of synovial biopsy specimens allow the prediction that RA will evolve from palindromic rheumatism,²⁵ although it may be worthwhile to measure ACPAs in these people.²⁶ Those who do not develop RA rarely have constitutional symptoms, and involved joints show no erosion because the synovitis does not become chronic. A more recent study of long-term outcomes in 60 patients diagnosed with palindromic rheumatism revealed that two-thirds of patients developed chronic arthritis, and the risk for chronic arthritis remained for longer than 10 years.²⁷ Of 51 patients with palindromic rheumatism, 41 experienced marked improvement in frequency and duration of attacks during treatment with antimalarials.²⁸ The use of antimalarials might reduce the risk of progression to RA.

Table 70-2 Evolution of Patients with Palindromic Rheumatism in Nine Series*

	No. of Cases	Remission or Cure (%)	Persistent PR (%)	RA (%)	Other Diseases (%)
Total or average	653	15 ± 14	48 ± 20	33 ± 17	4 ± 5

*In nine series of patients (653 total), the number undergoing remission or cure, remaining palindromic, evolving toward rheumatoid arthritis (RA), or developing another disease is expressed as an average percentage of the total patient population.

PR, Palindromic rheumatism; RA, rheumatoid arthritis.

Modified from Guerne P-A, Weisman MH: Palindromic rheumatism: part of or apart from the spectrum of rheumatoid arthritis, *Am J Med* 16:451-460, 1992. Copyright 1992, with permission from Excerpta Medica, Inc.

Insidious Onset in Older Individuals

Older individuals (≥ 65 years old) who develop RA often present with stiffness, limb girdle pain, and diffuse swelling of the hands, wrists, and forearms. Clinical onset that mimics polymyalgia rheumatica or remitting seronegative synovitis with pitting edema (RS3PE) also can occur in the elderly. Individuals with onset at age 60 years or older are less likely to have subcutaneous nodules or RF at the onset of disease, despite the high prevalence of RF in the general population in this age group. Generally, elderly individuals who develop RA tend to have a more benign course than younger people; the frequency of positive tests for RF is lower, but a strong association with HLA-DR4 has been noted. Onset is slow, but stiffness is often incapacitating.

In a study of patients with RA of less than 15 months' duration, older patients had higher scores for joint space narrowing and osteophytes at baseline than patients younger than 55 years. However, no evidence suggested that older patients had more rapid progression of damage, indicating that osteoarthritis was responsible for a significant portion of the damage noted at the onset of disease.²⁹

Arthritis Robustus

Arthritis robustus is not so much an unusual presentation of disease as an unusual reaction of patients to the disease.³⁰ Most patients are men whose disease is characterized by proliferative synovitis, often with deformity, which seems to cause little pain and even less disability. Patients are athletic and invariably keep working (often at physical labor). Peri-articular osteopenia is unusual, whereas new bone proliferation at joint margins near significant erosions of bone and cartilage is common. Bulky subcutaneous nodules develop. Subchondral cysts also develop, presumably from excessive pressure caused by synovial fluid within a thick joint capsule during muscular effort.

Rheumatoid Nodulosis

Whether rheumatoid nodulosis is a variant subset of RA or a different entity has not been clarified. The clinical picture includes recurrent pain and swelling in different joints, radiologic subchondral bone cysts, and subcutaneous rheumatoid nodules. In one series of 16 patients followed over 12 years, 6 had an aggressive course indistinguishable from classic erosive polyarticular RA. In 7 patients, cholesterol crystals were found in fluid from the olecranon bursae. Second-line drugs helped articular disease but did not help other components of the process.³¹

COURSE AND COMPLICATIONS OF ESTABLISHED RHEUMATOID ARTHRITIS

Involvement of Specific Joints: Effects of Disease on Form and Function

The effects of rheumatoid synovitis on joints are a complex function of the intensity of the underlying disease, its chronicity, and the stress put on individual joints by the patient. Most well-documented observations of specific joint involvement and of complications of the disease were

reported in the decades before 1980. Since then, these observations have been refined, but few new data have become available. Despite advances in our understanding of the pathophysiology of RA, including delineation of the cellular and enzymatic pathways that destroy joints, guidelines for the practicing physician—so that the probability that an individual patient would go on to develop erosive disease requiring aggressive treatment can be determined—are only in early stages of development. The spectrum of the clinical course of RA can range from patients who have mild pauciarticular synovitis, with negative serum auto-antibodies and few radiographic changes, to those who have unrelenting pain, synovitis, joint damage, and extra-articular manifestations.

Hands and Wrists

The hand and the wrist should be considered together because they form a functional unit. Data have linked disease of the wrist to ulnar deviation of the MCP joints.³² The hypothesis is that weakening of the extensor carpi ulnaris muscle leads to radial deviation of the wrist as the carpal bones rotate (the proximal row in an ulnar direction and the distal ones in a radial direction). In response to this, ulnar deviation of the fingers (a “zigzag” deformity) keeps the tendons to the phalanges in a normal line with the radius. Other factors, including the tendency for a power grasp to pull the fingers into an ulnar attitude and inappropriate intrinsic muscle action, are also involved (Figure 70-1). Erosion of bone or articular cartilage is not essential for the development of ulnar deviation (Figure 70-2). Significant but reducible ulnar deviation can result from repeated synovitis or muscle weakness in the hands (e.g., in systemic lupus erythematosus, in Parkinson's disease).

Dorsal swelling on the wrist within the tendon sheaths of the extensor muscles is one of the earliest signs of disease. Typically, the extensor carpi ulnaris and extensor digitorum communis sheaths are involved. Rarely, cystic structures resembling ganglia are early findings of RA.

As synovial proliferation develops within the wrist, pressure increases within the relatively nondistensible joint spaces. Proliferative synovium develops enzymatic machinery sufficient to destroy ligaments, tendons, and the articular disk distal to the ulnar head. Pressure and enzymes combine to produce communications among radiocarpal, radioulnar, and midcarpal joints. The integrity of the distal radioulnar joint is lost. The ulnar collateral ligament, stretched by the proliferative synovium of the radioulnar joint, finally ruptures or is destroyed, and the ulnar head springs up into dorsal prominence, where it “floats” and is easily depressed by the examiner's fingers (piano key styloid).

On the volar side of the wrist, synovial protrusion cysts develop; they can be palpated, and their origins can be confirmed by arthrography. The thick transverse carpal ligament provides significant resistance to decompression, however, and the hyperplastic synovium can compress the median nerve, causing carpal tunnel syndrome, often bilaterally.

Progression of disease in the wrist may be characterized by radiographic loss of joint space and bone or by ankylosis (Figure 70-3A). Ultrasound of the wrist correlates with function and classic signs of inflammation and is a

Figure 70-1 **A**, Polyarticular arthritis, especially with fusiform swelling of the proximal interphalangeal joints. Note deformity of wrists with radial deviation. **B**, Complete subluxation with marked ulnar deviation at the metacarpophalangeal joints in a patient with rheumatoid arthritis. The heads of the metacarpals are now in direct contact with the joint capsule instead of the proximal phalanges. (Courtesy Iain McInnes, MD.)

Figure 70-2 Ulnar deviation and subluxation. The hands show typical manifestations of end-stage erosive changes around the metacarpophalangeal joints, with volar dislocation and ulnar drift of the fingers. (Copyright A.L. Ladd.)

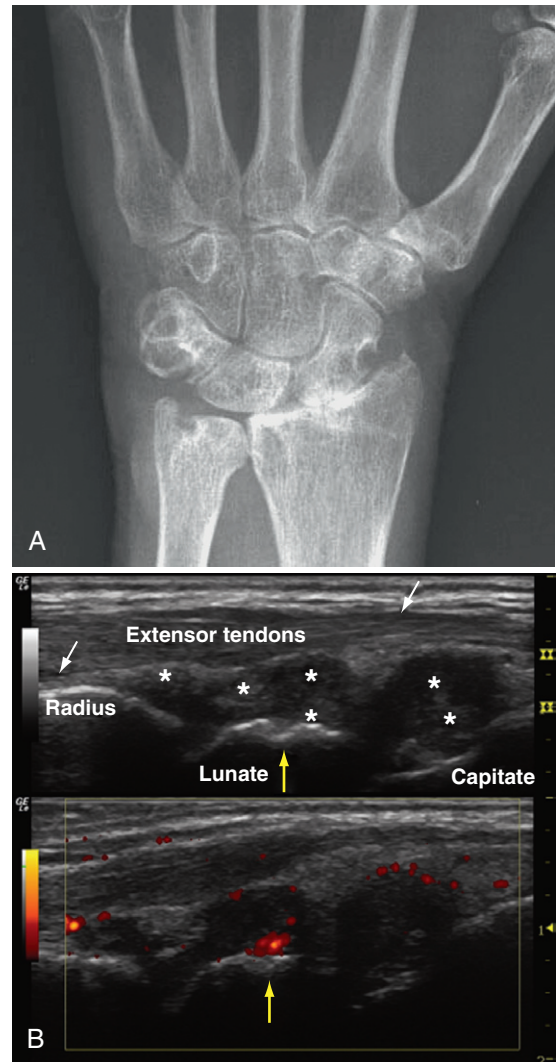

Figure 70-3 **A**, Typical sites of osseous erosion shown on radiographs of a rheumatoid wrist include triquetrum, pisiform, scaphoid, and radius. Erosions are also seen at the ulnar aspect of the distal radius and the distal ulnar styloid process secondary to involvement of the inferior radioulnar compartment. Diffuse cartilage loss is evident in the radiocarpal compartment. **B**, Ultrasound of the rheumatoid wrist dorsal longitudinal view shows synovial proliferation (*), tenosynovial thickening (white arrows), synovitis, and synovial hyperemia (yellow arrows). complementary tool in the evaluation of wrist arthritis in RA (Figure 70-3B). Early detection of carpal bone involvement by RA is also possible with magnetic resonance imaging (MRI), which reveals early synovial proliferation and carpal bone erosions. Bony ankylosis is associated with increased duration and severity of the disease and is found in joints that have been immobilized by pain, inflammation, treatment, or all of these.

The hand may have many joints involved in RA. A sensitive index of hand involvement is grip strength, which simultaneously stresses multiple hand joints. Muscular contraction causes ligamentous tightening around joints, compressing inflamed synovium. The immediate result is weakness, with or without pain; the reflex inhibition of muscular contraction due to pain may be a primary factor

in this weakness. Quantitative radiographic scores for joint space narrowing, erosion, and malalignment correlate well with loss of motion but do not correlate with joint count tenderness scores³³; these data support the concept that inflammatory synovitis and the erosive-destructive potential of proliferative synovitis in RA are not one and the same, but rather reflect different aspects of the same disease.

The swan neck deformity is one of flexion of the distal interphalangeal (DIP) and MCP joints with hyperextension of the PIP joint. The lesion probably begins with shortening of the interosseous muscles and tendons. Shortening of the intrinsic muscles exerts tension on the dorsal tendon sheath, leading to hyperextension of the PIP joint (Figure 70-4A).³⁴ Deep tendon contracture or, rarely, DIP joint involvement with RA leads to the DIP joint flexion. Marginal erosive changes in DIP joints occur more often in patients with RA who have coexisting osteoarthritis.³⁵

If, during chronic inflammation of a PIP joint, the extensor hood stretches or is avulsed, the joint may pop up in flexion, producing a boutonnière deformity (Figure 70-4B). The DIP joint remains in hyperextension.

The most serious result of rheumatoid involvement of the hand is severe resorption of bone that begins at the articular cartilage and spreads along the diaphysis of involved phalanges. Digits appear shortened, excess skin folds are present, and phalanges can be retracted (telescoped) into one another and then pulled out into abnormally long extension, often without pain. With the availability of more effective therapy for RA, this complication has become rare.

Figure 70-4 **A**, Swan neck deformity. This common deformity leads to hyperextension of the proximal interphalangeal joints and flexion of the distal interphalangeal joints. **B**, Boutonnière deformity. This deformity, which is the opposite of swan neck deformity, is marked by flexion of the proximal interphalangeal joints and extension of the distal interphalangeal joints. (Courtesy Iain McInnes, MD.)

Three types of deformity have been described for the thumb:

1. MCP inflammation leads to stretching of the joint capsule and a boutonnière-like deformity.
2. Inflammation of the carpometacarpal joint leads to volar subluxation during contracture of the adductor hallucis.
3. After prolonged disease of both MCP joints, exaggerated adduction of the first metacarpus, flexion of the MCP joint, and hyperextension of the DIP joint result from the patient's need to provide a means to pinch.

One of the most common manifestations of RA in the hands is tenosynovitis in flexor tendon sheaths; this can be a major cause of hand weakness.³⁶ Tenosynovitis manifests on the volar surfaces of the phalanges as diffuse swelling between joints or as a palpable grating within flexor tendon sheaths in the palm and may occur in half of RA patients.

It is particularly important to diagnose de Quervain's tenosynovitis of the extensors of the thumb because this condition causes severe discomfort and yet is easily treated. Pain originating from these sheaths can be shown by Finkelstein's test, that is, ulnar flexion at the wrist after the thumb is maximally flexed and adducted.

Frequently, rheumatoid nodules develop within tendon sheaths and may "lock" the finger painfully into fixed flexion or cause "trigger" fingers. When they are chronic or recurrent, it may be necessary to inject the tendon sheath or, if that fails, to remove it surgically.

Elbows

RA rarely manifests with severe pain in the elbow, perhaps because the elbow is a stable hinge joint. Nevertheless, involvement of the elbow is common, and if lateral stability at the elbow is lost as the disease progresses, disability can be severe.

The frequency of elbow involvement varies from 20% to 65%, depending on the severity of disease in the patient populations studied. One of the earliest findings, often unnoticed by the patient, is loss of full extension. Because the elbow is principally a connecting joint between the hand and the trunk, the shoulder and the wrists can compensate partially for the loss of elbow motion.

Shoulders

RA of the shoulder not only affects synovium within the glenohumeral joint but also involves the distal third of the clavicle, various bursae and the rotator cuff, and multiple muscles around the neck and chest wall. Severe shoulder pain is often bilateral and can lead to sleep disorders because of difficulty finding a comfortable position. Involvement of the rotator cuff in RA also has been recognized as a principal cause of morbidity. The function of the rotator cuff is to stabilize the humeral head in the glenoid. Weakness of the cuff results in superior subluxation. Rotator cuff tears or insufficiency from other causes can be shown by shoulder arthrography or MRI. In a series of 200 consecutive patients with RA studied by arthrography, 21% had rotator cuff tears, and an additional 24% had evidence of frayed

Figure 70-5 Abnormalities of the shoulder in rheumatoid arthritis. The Grashey posterior oblique view of a shoulder shows severe glenohumeral joint space narrowing with marginal erosion and cystic changes of the humeral head adjacent to the greater tuberosity (*lower arrow*). Elevation of the humeral head with respect to the glenoid indicates chronic rotator cuff tear. Tapering of the distal end of the clavicle is seen, along with widening of the acromioclavicular joint (*upper arrow*). (Courtesy Dr. Barbara Weissman.)

tendons.³⁷ One likely mechanism behind tears is that the rotator cuff tendon insertion into the greater tuberosity is vulnerable to erosion by the proliferative synovitis that develops there. Previous injury and aging may predispose to the development of tears. Sudden tears may be accompanied by pain and inflammation so great as to suggest infection.

Standard radiographic examinations of the shoulder in RA reveal erosions and superior subluxation (Figure 70-5). Arthrograms, in addition to showing tears of the rotator cuff, can show diffuse nodular filling defects, irregular capsular attachment, bursal filling defects, adhesive capsulitis, and dilation of the biceps tendon sheath (perhaps unique to RA).³⁸ High-resolution computed tomography (CT) or MRI may provide much of this information without the need for invasive techniques.

Marked soft tissue swelling of the anterolateral aspect of the shoulders in RA may be caused by chronic subacromial bursitis rather than by glenohumeral joint effusions. In contrast to rotator cuff tears, bursal swelling is not associated with decreased range of motion or pain. Synovial proliferation within the subdeltoid bursa might explain the resorption of the undersurface of the distal clavicle seen in this disease. Rarely, the shoulder joint may rupture, with symptoms resembling those of obstruction of venous return from the arm.

Temporomandibular Joints

The temporomandibular joint is commonly involved in RA. Histories reveal that 55% of patients have jaw

symptoms at some time during the course of their disease. Radiographic examination reveals structural alterations in 78% of the joints examined. An overbite can develop as the mandibular condyle and the corresponding surface of the temporal bone, the eminentia articularis, are eroded. Physical examination of the rheumatoid patient should include palpation of the temporomandibular joint for tenderness and auscultation for crepitus. Occasionally, patients have acute pain and an inability to close the mouth, necessitating intra-articular glucocorticoid therapy to suppress the acute process.

Temporomandibular joint abnormalities are common in nonrheumatoid populations. The only specific findings for RA in the temporomandibular joint are erosions and cysts of the mandibular condyle detected by CT or MRI. No correlation has been noted between clinical and CT findings of the temporomandibular joint in RA.³⁹

Cricothyroid Joints

The cricothyroid joints are small diarthrodial joints with an important function: They rotate with the vocal cords as the vocal cords abduct and adduct to vary the pitch and tone of the voice. Careful histories may reveal hoarseness in 30% of rheumatoid patients. This hoarseness is not disabling in itself, but the cricothyroid joints may become inflamed and immobilized, with the vocal cords adducted to the midline, causing inspiratory stridor. Autopsy examinations have shown cricothyroid arthritis in almost half of patients with RA, suggesting that much significant disease of the larynx may be asymptomatic. Although CT scans detected laryngeal abnormalities in 54% of patients with moderately severe RA, no symptoms suggested that these abnormalities would be found.⁴⁰ In contrast, findings on indirect laryngoscopy, which detected mucosal and gross functional abnormalities (including rheumatoid nodules), were abnormal in 32% of the same patients and correlated with symptoms of sore throat and difficult inspiration. It follows that the latter examination should be performed in symptomatic rheumatoid patients. Asymptomatic cricothyroid synovitis occasionally may lead to aspiration of pharyngeal contents, particularly at night.

Sternoclavicular and Manubriosternal Joints

Sternoclavicular and manubriosternal joints, both possessing synovium and a cartilaginous disk, are often involved in RA. Because of their relative immobility, few symptoms are reported. Patients occasionally describe pain in the sternoclavicular joints, however, while lying on their sides in bed. When symptoms do occur, the physician must be concerned about superimposed sepsis. CT or MRI is useful for careful delineation of the sternoclavicular joint. Manubriosternal involvement is almost never clinically important, although by tomographic criteria, it is common in RA.

Cervical Spine

In contrast to other nonsynovial joints, such as the manubriosternal joint or the symphysis pubis, diskovertebral joints in the cervical spine often manifest osteochondral destruction in RA and on lateral radiographs may be found

Figure 70-6 Rheumatoid arthritis of the cervical spine. **A**, Lateral radiograph in flexion shows severe anterior atlantoaxial subluxation with a wide anterior atlantodental interval (asterisks) and a decreased posterior atlantodental interval (arrow). **B**, Almost complete reduction of subluxation is noted on the lateral view in extension. Subaxial subluxation is evident at the level of C4-C5 (arrowheads) with erosive changes in various facet joints. O, odontoid. (Courtesy Dr. Barbara Weissman.)

to be narrowed (Figure 70-6). Significant pain is reported, but passive range of motion in the absence of muscle spasm may be normal. At least two possible mechanisms have been put forth for this process: (1) extension of the inflammatory process from adjacent neurocentral joints (the joints of Luschka), which are lined by synovium, into the discovertebral area, and (2) chronic cervical instability initiated by apophyseal joint destruction leading to vertebral malalignment or subluxation. This process may produce microfractures of the vertebral end plates, disk herniation, and degeneration of disk cartilage. The atlantoaxial joint is prone to subluxation in several directions and is summarized later.

- The atlas can move anteriorly on the axis (most common). This results from laxity of the ligaments induced by the development of proliferative synovial tissue in adjacent synovial bursae or by fracture or erosion of the odontoid process.
- The atlas can move posteriorly on the axis. This can occur only if the odontoid peg has been fractured from the axis or destroyed.
- The atlas can sublux vertically in relation to the axis (least common). This results from destruction of the lateral atlantoaxial joints or of bone around the foramen magnum. Vertical (superior) migration of the odontoid can develop from unattended anterior or posterior subluxation.

The earliest and most common symptom of cervical subluxation is pain radiating up into the occiput. Two other serious, but less common, clinical patterns include slowly progressive spastic quadriplegia with painless sensory loss in the hands and transient episodes of medullary dysfunction associated with vertical penetration of the dens and

probable vertebral artery compression. In the latter, paresthesias may occur in the shoulders or arms during movement of the head.

Physical findings suggestive of atlantoaxial subluxation include loss of occipitocervical lordosis, resistance to passive spine motion, and abnormal protrusion of the axial arch felt by the examining finger on the posterior pharyngeal wall. Radiographic views (lateral, with the neck in flexion) reveal more than 3 mm of separation between the odontoid peg and the axial arch. In symptomatic patients, films in flexion should be taken only after radiographs (including an open-mouth posteroanterior view) have ruled out an odontoid fracture or severe atlantoaxial subluxation. Studies have indicated that CT is useful for showing spinal cord compression by loss of posterior subarachnoid space in patients with C1 to C2 subluxation. MRI has proved particularly valuable in determining pathologic anatomy in this syndrome (Figure 70-7).

Neurologic symptoms often have little relationship to the degree of subluxation and may be related to individual variations in the diameter of the spinal canal. Symptoms of spinal cord compression that demand intervention include altered consciousness, syncope, and loss of sphincter control. Dysphagia, vertigo, convulsions, hemiplegia, dysarthria, nystagmus, and peripheral paresthesias are additional symptoms that require immediate attention.

Some of these symptoms may be related to compression of the vertebral arteries, which must wind through foramina in the transverse processes of C1 and C2, rather than to compression of the spinal cord.

The progression of peripheral joint erosions parallels cervical spine disease in RA. The two coincide in severity and timing; cervical subluxation is more likely to develop

Figure 70-7 Rheumatoid arthritis of the cervical spine. T2-weighted sagittal image shows low signal periodontoid pannus (P). Odontoid process appears irregular secondary to erosion (arrow). The atlantodental distance shows mild widening (solid line). Vertical subluxation can also be seen without signs of cord compression. The anterior subarachnoid space is compromised by disk protrusions at multiple levels. Erosions (arrowheads) are seen at the vertebral end plates at the C6-C7 level. (Courtesy Dr. Barbara Weissman.)

in patients with erosion of the hands and feet. In a series of patients with RA referred for hip or knee arthroplasty, 61% had radiographic evidence of cervical spine instability.⁴¹

Is mortality increased in patients with atlantoaxial subluxation? Neurologic signs do not inevitably develop in patients with large subluxations. When signs of cervical cord compression do appear, however, myelopathy progresses rapidly, and 50% of patients die within 1 year.⁴² These patients are at risk for these complications if they sustain small falls, whiplash injuries, and general anesthesia with intubation. Cervical collars can be prescribed for symptomatic relief. Operative stabilization may be considered if symptoms are progressive.

Some data support the hypothesis that early C1-to-C2 fusion for atlantoaxial subluxation before the development of superior migration of the odontoid decreases the risk for further progression of cervical spine instability.⁴³ The incidence of sustained neurologic deterioration related to surgery may be 6%; this emphasizes the importance of a skilled surgical team and of careful assessment of each patient. In many cases, surgical intervention in asymptomatic patients is riskier than conservative management despite the dire appearance of imaging studies.

Vertical atlantoaxial subluxation is important and may follow anterior or posterior subluxation. Symptoms associated with this collapse of the lateral support system of the atlas occur in patients with severe erosive disease. Neurologic findings include decreased sensation in the distribution of cranial nerve V, sensory loss in the C2 area, nystagmus, and pyramidal lesions.

Thoracic, Lumbar, and Sacral Spine

The thoracic, lumbar, and sacral portions of the spine are usually spared in RA. Exceptions include the apophyseal joints; rarely, synovial cysts at the apophyseal joint can impinge as an epidural mass on the spinal cord, causing pain, neurologic deficits, or both.

Hips

The hip is less frequently involved in early RA than in juvenile RA. Hip joint involvement must be ascertained by careful clinical examination; symptoms of hip synovitis include pain in the lower buttock or, more commonly, the groin. Pain on the lateral aspect of the hip is often a manifestation of trochanteric bursitis rather than true hip joint synovitis.

About half of patients with well-established RA have radiographic evidence of hip disease. In contrast to osteoarthritis, in which the femoral head usually migrates superiorly, symmetric thinning of the cartilage in RA leads to axial migration. The femoral head may collapse and be reabsorbed, and the acetabulum is remodeled and pushed medially, leading to protrusio acetabuli (Figure 70-8). Significant protrusion occurs in about 5% of all patients with RA.⁴⁴ Loss of internal rotation on physical examination correlates best with radiographic findings. Similar to the situation in other weight-bearing joints, the femoral head may develop cystic lesions that communicate with the joint space.

Knees

In contrast to the hips, synovial inflammation and proliferation in the knees are readily shown on physical examination. Early in knee disease, often within 1 week after the onset of symptoms, noticeable quadriceps atrophy leads to the application of more force than usual through the patella

Figure 70-8 Bilateral protrusio acetabuli in rheumatoid arthritis. The medial acetabular margins protrude into the pelvis. Severe accompanying cartilage loss is evident. (Courtesy Dr. Barbara Weissman.)

to the femoral surface. Another early manifestation of knee disease in RA is loss of full extension—a functional loss that can become a fixed flexion contracture unless corrective measures are undertaken.

Flexion of a knee with a moderate to large effusion markedly increases intra-articular pressure. The increased intra-articular pressure may cause an outpouching of posterior components of the joint, producing a popliteal or Baker's cyst. This can generate pressures so high in the popliteal space that it may rupture down or dissect into the calf or, less often, superiorly into the posterior thigh. Rupture occurs posteriorly between the medial head of the gastrocnemius and the tendinous insertion of the biceps. Clinically, popliteal cysts and their complications have several manifestations. An intact popliteal cyst may compress superficial venous flow from the lower leg, producing dilation of superficial veins, edema, or both.⁴⁵ Rupture of the joint posteriorly with extravasation of joint fluid into the calf may resemble acute thrombophlebitis with swelling and tenderness and may produce systemic signs of fever with leukocytosis. One helpful sign in identifying cyst rupture may be the appearance of a crescentic hematoma beneath one of the malleoli of the ankle.⁴⁶ Although arthrography clearly defines the abnormal anatomy of a Baker's cyst, this invasive procedure has been replaced by ultrasonography and, when necessary, MRI (Figure 70-9).

Ankles and Feet

Ankle involvement is usually mild in RA, but damage can occur in severe progressive forms of the disease. Clinical evidence for ankle involvement consists of cystic swelling anterior and posterior to the malleoli. Much of the stability of the ankle depends on the integrity of the ligaments

Figure 70-9 Magnetic resonance imaging (MRI) of the knee in rheumatoid arthritis. Sagittal fast spin echo T2-weighted fat-suppressed image allows excellent contrast. Synovial fluid is shown in white as a posterior fluid collection. (Courtesy Dr. Barbara Weissman.)

Figure 70-10 Rheumatoid arthritis of the ankle. Diffuse loss of cartilage space can be seen with erosion of the fibula (arrows). Scalloping along the medial border of the distal fibula is designated the fibular notch sign and is a characteristic finding in rheumatoid arthritis. The hindfoot is in valgus alignment.

holding the fibula to the tibia and these two bones to the talus. In RA, inflammatory and proliferative disease may loosen these connections by stretching and eroding the collagenous ligaments, causing erosions (Figure 70-10). The result is incongruity, which progresses to pronation deformities and eversion of the foot.

The Achilles tendon is a major structural component and kinetic force in the foot and ankle. Rheumatoid nodules develop in this collagenous structure, and spontaneous rupture of the tendon has been reported when diffuse granulomatous inflammation is present.⁴⁷ The subtalar joint controls eversion and inversion of the foot on the talus; patients with RA invariably have more pain while walking on uneven ground; this is related to the relatively common subtalar joint involvement in RA. Progressive eversion at the subtalar joint, combined with foot pain, leads to a lateral subluxation beginning in the midfoot and the development of a rocker-bottom deformity. Midfoot disease leads to collapse of the arch, which contributes to difficulty walking because of pain.

More than one-third of patients with RA have significant disease in the feet (Figure 70-11). Metatarsophalangeal (MTP) joints are often involved, and gait is altered as pain develops during push-off in striding. Studies have shown that MTPs are the initial site of erosion in many patients. Downward subluxation of the metatarsal heads occurs soon after the MTP joints become involved, producing “cock-up” toe deformities of the PIP joints. Hallux valgus and bunion or callus formation occur if disease continues. Cystic collections representing outpouchings of flexor tendon sheaths often develop under the MTP joints.⁴⁸

Figure 70-11 Valgus of ankle, pes planus, and forefoot varus deformity of the left foot related to painful synovitis of the ankle, forefoot, and metatarsophalangeal joint in a 24-year-old man with severe rheumatoid arthritis.

Patients with subluxation of metatarsal heads can develop pressure necrosis of the plantar surfaces. Alternatively, those who have subluxation of MTP joints often develop ulceration over the PIP joints that protrude dorsally (hammer toes). The net result is increased pressure on the MTP joints with a sensation described as “walking on marbles” by many patients. Changes caused by the progress of disease and destruction in the foot include intermetatarsal joint ligament stretching in response to inflammation, spreading of the forefoot, anterior migration of the plantar fat pad, and dorsal subluxation of toes followed by plantar subluxation of the metatarsal heads.⁴⁹ Concurrently, hallux valgus results in progressive overlap of the second and third toes on top of the great toe.

DIP joints of the foot are rarely affected in RA, but a functional rigid hallux caused by muscle spasm of the great toe intrinsic muscles in an effort to relieve pressure on the lesser metatarsal heads can be extremely painful and may require surgical intervention. Another cause of foot pain in rheumatoid patients is the tarsal tunnel syndrome. In a group of 30 patients with RA, erosions in the feet visible on radiographs and foot pain (4 patients; 13%) were shown by electrodiagnostic techniques to produce slowing of medial or lateral plantar nerve latency, or both.

Extra-articular Complications of Rheumatoid Arthritis

Generally, the number and severity of extra-articular features vary with the duration and severity of the disease. Several of these features may be related to extra-articular foci of an immune response,⁵⁰ based on evidence of independent and qualitatively different production of RF in the pleural space, pericardium, muscle, and even meninges. Patients with systemic immune responses have true rheumatoid disease, not just RA. Other unusual proteins and protein complexes in the circulation of patients with active rheumatoid disease include antiphospholipid antibodies, circulating immune complexes, and cryoglobulins. Extra-articular manifestations of RA are associated with excess mortality.⁵¹

Rheumatoid Nodules

The mature rheumatoid nodule has a central area of necrosis rimmed by a corona of palisading fibroblasts that is surrounded in turn by a collagenous capsule with perivascular collections of chronic inflammatory cells. The earliest nodules, nests of granulation tissue, have been identified measuring less than 4 mm. These nodules grow by accumulating cells that expand centrifugally, leaving behind central necrosis initiated by vasculopathy and compounded by protease destruction of the connective tissue matrix. Nodules occur in 15% to 20% of patients with definite arthritis or RA. They occur most often on extensor surfaces or pressure points, such as the olecranon process and the proximal ulna (Figure 70-12A), as well as on tendons (Figure 70-12B). They are subcutaneous and vary in consistency from a soft, amorphous, entirely mobile mass to a hard, rubbery mass attached firmly to the periosteum.

The appearance of nodules in unusual sites can lead to confusion in diagnosis; they sometimes can appear identical to other types of nodules such as tophi. Sacral nodules may be mistaken for bedsores if the overlying skin breaks down. Occipital nodules also occur in bedridden patients. In the larynx, rheumatoid nodules on the vocal cords may cause progressive hoarseness. Nodules can even be found in the heart and lungs (see later). Nodules on the sclera can produce perforation of this collagenous tissue. Multiple reports describe rheumatoid nodule formation within the central nervous system, involving leptomeninges more frequently than parenchyma.⁵² Some patients develop rheumatoid nodules within vertebral bodies, resulting in bone destruction and signs of myelopathy.

Careful histologic study of early lesions⁵³ suggests that development of the nodule is mediated by affected small arterioles and resulting complement activation and terminal vasculitis. This immunologic response is linked to proliferation of resident histiocytes and fibroblasts and to an influx of macrophages from the circulation. Proliferation of cells and the supporting scaffold of connective tissue are mediated by cytokines expressed in patterns similar to those found in rheumatoid synovium. The cytokine profile of the rheumatoid nodule suggests a T helper-1 (Th1) gene expression pattern similar to that of synovial tissue, including expression of tumor necrosis factor (TNF), interleukin (IL)-1, IL-12, and interferon (IFN)- γ , but not IL-2. More recently, gene expression of IL-17 family members in rheumatoid nodules showed that IL-17A gene expression was minimal in contrast to that of rheumatoid synovial tissue.⁵⁴ The absence of IL-17A could be due to decreased IL-23 expression in the nodule. Data from studies using monoclonal antibodies against receptors for complement C3b and C3bi, monocytes, activated macrophages, and HLA-DR molecules suggest that mononuclear phagocytes are constantly being recruited into peripheral layers and subsequently migrate into the palisade to constitute most of the cell population in this area.⁵⁵ Other studies using cytochemical markers (nonspecific esterase and CD68 for macrophages, and prolyl hydroxylase for fibroblasts) indicate that a mixture of macrophages and fibroblasts makes up the cellular content of nodules.⁵⁶ This evidence fits with data from nodule tissue in organ culture; similar to synovial tissue, cells in the palisading region have

Figure 70-12 Manifestations of increased reactivity of mesenchymal tissue in rheumatoid arthritis include nodules on the elbow (**A**) and on the Achilles tendon (**B**), as well as episcleritis (**C**) and scleromalacia (**D**). (Courtesy Iain McInnes, MD.)

the capacity to produce collagenase and protease in large quantities.⁵⁷

RF is almost always found in the serum of patients with rheumatoid nodules. Rarely, such nodules are present in the absence of obvious arthritis. A condition called *rheumatoid nodulosis* is characterized by the presence of multiple nodules on the hands, a positive test for RF, episodes of acute intermittent synovitis, and subchondral cystic lesions of small bones of the hands and feet.⁵⁸ Many clinicians have noted that during methotrexate therapy, existing nodules may enlarge and new ones may develop, even though symptoms of synovitis regress; the pathophysiology underlying this phenomenon is unknown, although it may relate to the effects of methotrexate on adenosine (see Chapter 61). Discontinuing methotrexate in these patients usually leads to regression of some nodules. Some case reports suggest that TNF inhibitors can be associated with accelerated rheumatoid nodulosis.

The differential diagnosis of rheumatoid nodules includes benign nodules usually found in healthy children that are nontender and appear on the pretibial regions, feet, and scalp. In addition, nodular changes can occur in subcutaneous nodules as rheumatic fever, Gottron's papules in dermatomyositis, and calcinosis in scleroderma. Granuloma annulare consists of intracutaneous nodules that are histologically identical to rheumatoid nodules. Nodules due to xanthomatosis usually have a yellow tinge, and patients have abnormally high plasma lipoprotein and cholesterol levels. Tophi, which are collections of monosodium urate crystals in patients with gout, are associated with small,

punched-out bone lesions and almost always occur in the presence of elevated serum urate concentration. Nodules of multicentric reticulohistiocytosis contain large, lipid-filled macrophages. Numerous proliferative disorders that affect cutaneous tissue, including erythema elevatum diutinum, acrodermatitis chronica atrophicans, bejel, yaws, pinta, and leprosy, can resemble rheumatoid nodules. A rheumatoid nodule, particularly when it occurs on the face, may simulate basal cell carcinoma.

Bone Density

The skeleton has two anatomically and functionally separate components, cortical and trabecular bone, which respond differently to systemic and local diseases and to drugs. RA can be associated with generalized osteopenia and osteoporosis owing to the effects of drugs (especially corticosteroids); cytokine-induced and receptor activator of nuclear factor κ B (NF κ B) ligand (RANKL)-induced activation of osteoclasts; and the fact that certain groups of patients with the disease, especially postmenopausal women, have other risk factors that enhance the potential for bone loss. Risks for hip fracture and vertebral compression fracture can be high. Bone densitometry should be performed routinely in patients with RA; treatment with bisphosphonates should be considered as an adjunct to therapy.

Because postmenopausal women are at greater risk for osteoporosis, this group should be treated aggressively. Minimizing steroid use is one method that can be used to decrease the risk of osteoporosis in this group and in other

patients with RA. Two-phase loss of bone seems to be induced by glucocorticoids: a rapid first phase, when 12% of bone mass disappears in the first 6 to 12 months of therapy, followed by a subsequent chronic phase, which has a slower rate of bone loss.⁵⁹ It is encouraging that axial bone loss in patients with RA induced early by glucocorticoids can be reversed.⁶⁰ The evaluation, biology, and management of osteoporosis are discussed in Chapter 101. In the relationship between RA and bone, the focus is, appropriately, on osteoporosis; however, diffuse loss of bone in RA, whether or not it is related to glucocorticoid therapy, leads to a high incidence of stress fractures of long bones in RA.⁶¹ The fibula is the most common fracture site. Acute leg pain in a thin, elderly rheumatoid patient, even without a history of trauma, should generate suspicion of a stress fracture. Geodes (i.e., subchondral cysts developed by synovial penetration of the cortex or subchondral plate and subsequent proliferation) weaken bone and can predispose bone to fracture.

Muscle

Clinical weakness is common in RA, but is it caused by muscle involvement in rheumatoid inflammation, or is it a reflex weakness response to pain? Most rheumatoid patients have muscle weakness, but few have muscle tenderness or elevated muscle enzymes in the blood.

In an early autopsy series, focal accumulations of lymphocytes and plasma cells with some contiguous degeneration of muscle fibers were found in all rheumatoid patients—a condition termed *nodular myositis*. More recent studies have pointed to multiple types of muscle disease in RA, although clinically relevant active myositis is uncommon⁶²:

- Diminution of muscle bulk with atrophy of type II fibers
- Peripheral neuromyopathy, usually due to a mononeuritis multiplex
- Steroid myopathy
- Active myositis and muscle necrosis with foci of endomysial mononuclear cell infiltration
- Chronic myopathy resembling a dystrophic process, probably the end stage of inflammatory myositis

In biopsy specimens, atrophy of type II fibers is most common. Evidence of myositis and focal necrosis is found occasionally in biopsy specimens of patients with active disease, particularly in a subset with mild synovitis and a disproportionately high erythrocyte sedimentation rate (ESR). In some patients, the lymphocytes in muscle synthesize IgM RF, emphasizing the systemic nature of RA. The patchy “nodules of myositis” contain plasma cells and lymphocytes.

Skin

The most frequently recognized skin lesion in RA is the rheumatoid nodule but several other manifestations may be observed as well. “Senile” purpura resulting from skin atrophy and capillary fragility is especially common in patients treated with glucocorticoids. Palmar erythema is common, but Raynaud’s syndrome is rare. Manifestations of vasculitis range from occasional nail fold infarcts to a deep, erosive, scarring pyoderma gangrenosum. Palpable purpura

in rheumatoid patients often occurs as a reaction to a drug that the patient is taking but can be primary and a direct function of the severity of articular disease. Livedo reticularis, the lacy, dusky purple, asymptomatic discoloration seen on the extremities, is believed to signify a deep dermal vasculopathy. It can be present in any or all diffuse connective tissue diseases and often is associated with antiphospholipid antibodies.⁶³

Eye

Virtually all ocular manifestations of RA can be considered complications of the disease (see Chapter 44). Keratoconjunctivitis sicca, a component of Sjögren’s syndrome, is discussed in Chapter 73. Scleritis and episcleritis are associated with RA. Highly differentiated connective tissues in the eye make rheumatoid manifestations particularly interesting and, when they occur in aggressive form, very serious.

The episclera of the eye is highly vascular compared with the dense sclera. Scleritis, episcleritis, or both occur in less than 1% of rheumatoid patients. In episcleritis, the eye becomes red and, in contrast to conjunctivitis, causes tearing but no discharge. Loss of vision does not occur as a direct result of episcleritis, but a keratitis or a cataract developing secondarily can cause visual loss. Scleritis causes severe ocular pain and dark red discoloration (Figure 70-12C). No discharge is present. Depending on the intensity of the process, scleritis can be localized and superficial or generalized, with or without granulomatous resorption of the sclera down to the uveal layer; when this complication occurs, it is termed *scleromalacia perforans*. In contrast to superficial eye disease, which usually can be treated conservatively with topical steroids, scleritis usually requires systemic or intraocular corticosteroid treatment. In some cases, the sclera can become thin even in the absence of overt inflammation, leading to scleromalacia (Figure 70-12D). Rarely, perilimbic ischemic ulcers can be caused by cryoproteins (RF-IgG complexes) and if untreated can result in perforation of the anterior chamber. Patients with RA who have an associated keratoconjunctivitis sicca secondary to Sjögren’s syndrome have pruritic and painful eyes, sometimes leading to chronic blepharitis.

Host Defense and Infection

The incidence of infection as a complication of RA has paralleled the use of glucocorticoids, biologics, and immunosuppressive agents. TNF blockers are especially noteworthy because they have been associated with reactivation of tuberculosis and other opportunistic infections such as histoplasmosis. Pulmonary infections, skin infections, and septic arthritis are the most common infections in RA.^{64,65} Difficulty in diagnosis is accentuated by the similarity of aggressive RA to infection, particularly in joints; a “pseudo-septic” arthritis in rheumatoid patients, associated with fever, chills, and grossly purulent synovial fluid, can be part of a severe exacerbation of RA and must be distinguished from infection.⁶⁶ Mortality attributable to respiratory infections such as pneumonia and bronchitis is increased in RA patients compared with the general population.⁶⁷ A retrospective longitudinal cohort study compared the frequency of infection in a population-based incidence cohort

of RA patients versus that in a group of individuals without RA from the same population; this study looked at 7900 to 9100 person-years.⁶⁸ A total of 609 RA patients and 609 non-RA patients were studied; 73% were women, and mean patient age was 58 years. Hazard ratios for RA patients versus controls after adjustment for age, sex, smoking status, leukopenia, corticosteroid use, and diabetes mellitus were nearly twofold increased for confirmed infection and for infection requiring hospitalization. Bone, joints, skin, respiratory tract, and soft tissues were the organs with highest hazard ratios. In a subsequent study in this cohort, predictors of infection were identified as increasing age, extra-articular manifestations of RA, leukopenia, and comorbidities such as chronic lung disease, alcoholism, diabetes mellitus, and the use of glucocorticoids.

Traditional DMARD use generally is not associated with a major increased incidence of infection. However, vigilance in using biologic agents is essential because mortality is increased from infection due to immunosuppression.⁶⁹ Physicians should always have a low threshold of concern for infection in rheumatoid patients.

Hematologic Abnormalities

Most patients with active RA have a mild normocytic normochromic anemia that correlates with ESR elevation and the activity of the disease. Anemia has mixed causes in RA. One deficiency may mask evidence of others. A useful guide is that three-quarters of rheumatoid patients with anemia have the anemia of chronic disease, whereas one-quarter respond to iron therapy. Patients in both groups may have superimposed vitamin B₁₂ or folate deficiency.⁷⁰ Hemoglobin of less than 10 is rarely due only to RA. The following guidelines may prove helpful to the clinician in diagnosing the cause of anemia in rheumatoid patients:

- Anemia of chronic disease is associated with a significantly higher serum ferritin concentration than is found in isolated iron deficiency.
- Folate or vitamin B₁₂ deficiency or the use of methotrexate can mask iron deficiency, especially in patients taking nonsteroidal anti-inflammatory drugs (NSAIDs) with chronic gastrointestinal blood loss, by increasing the mean cell volume and the mean cell hemoglobin level of erythrocytes.
- The ESR correlates inversely with hemoglobin levels in RA.
- Erythropoietin levels are higher in patients with iron deficiency anemia compared with those with anemia of chronic disease; rheumatoid patients have a diminished response to erythropoietin.⁷¹

In patients with anemia of chronic disease, the total erythroid heme turnover is slightly reduced, and ineffective erythropoiesis accounts for a much higher than normal percentage of total heme turnover. In contrast to anemia associated with blood loss, ineffective erythropoiesis returns to normal in RA if remission can be induced.⁷² Red blood cell aplasia, immunologically mediated, is a rare finding in RA.

Thrombocytosis is often associated with RA. A significant relationship has been noted between thrombocytosis and extra-articular manifestations of rheumatoid disease and disease activity.⁷³ Eosinophilia (5% of total white blood cell count) has been observed in some patients.

Felty's syndrome comprises an uncommon but severe subset of seropositive, erosive RA symptoms that occur in patients with neutropenia and splenomegaly. Patients with Felty's syndrome have more frequent and robust extra-articular RA manifestations and are at increased risk for infection, skin ulceration, and other complications. Another subset of patients with RA includes those with increased numbers of large granular lymphocytes in the peripheral blood, bone marrow, and liver. These lymphocytes contain many azurophilic granules in the cytoplasm and may account for more than 90% of mononuclear cells in blood. They are increased in certain viral infections. The cells are Fc receptor positive, do not produce IL-2, respond poorly to mitogens, and involve antibody-dependent cell-mediated cytotoxicity activity (expressing CD3, CD8, and CD57) or natural killer cells (expressing CD16 and CD56).^{74,75} Among previously described patients with large granular lymphocyte proliferation, almost one-third have had RA.⁷⁶ Because the large granular lymphocyte syndrome in patients with RA has the same HLA-DR4 association seen in Felty's syndrome, the proposal has been made that Felty's syndrome and large granular lymphocyte syndrome represent different variants of a broader syndrome comprising RA, neutropenia, large granular lymphocyte expansions, HLA-DR4 positivity, and variable splenomegaly.⁷⁷ Neutropenia has been described as an adverse event in more recent drug trials in RA patients, most notably with the humanized anti-IL-6 receptor monoclonal antibody tocilizumab.⁷⁸

Paraproteinemia, typified by monoclonal gammopathies, has a poor prognostic significance when it appears in rheumatoid patients. This evidence for monoclonal B cell proliferation carries with it a high frequency of malignant transformation to lymphoma or myeloma.⁷⁹

Vasculitis

The initial pathologic change in RA is often seen as inflammatory changes in medium and small blood vessels. It is useful to use the term *vasculitis* to group extra-articular complications related not to proliferative granulomas, but rather to inflammatory vascular disease. Systemic rheumatoid vasculitis, one of the most feared complications of RA, has become increasingly uncommon in recent years. This decline in rheumatoid vasculitis, similar to many other extra-articular manifestations, is likely related to marked improvement in therapy resulting from widespread use of methotrexate and new biologic agents. Male gender, longstanding disease, high-titer RF in serum, hypocomplementemia, erosive disease, circulating cryoglobulins, deposition of immune complexes and complement in blood vessels, and extra-articular features such as subcutaneous nodules are variables associated with the development of rheumatoid vasculitis.⁸⁰

Rheumatoid vasculitis affects a very small subset of patients with established, often severe, RA. It can present as the following:

- Distal arteritis (including from splinter hemorrhage, nail fold infarcts, and gangrene) (Figure 70-13)
- Cutaneous ulceration (including pyoderma gangrenosum)
- Peripheral neuropathy (mononeuritis multiplex or sensory stocking-glove neuropathy)

Figure 70-13 A, Digital vasculitis in a 65-year-old man with seropositive rheumatoid arthritis. B, Nail fold infarcts can occur in patients with rheumatoid arthritis and typically are associated with rheumatoid factor positivity and active joint disease. (A, Courtesy Eileen Moynihan, MD.)

- Palpable purpura
- Arteritis of viscera, including heart, lungs, bowel, kidney, liver, spleen, pancreas, lymph nodes, or testis

The pathologic finding in rheumatoid vasculitis is a panarteritis. All layers of the vessel wall are infiltrated with mononuclear cells. Fibrinoid necrosis is seen in active lesions. Intimal proliferation may predispose to thrombosis. Obliterative endarteritis of the finger is a common manifestation of vasculitis, and immune complex deposits have been shown in affected vessels.⁸¹ In patients with hypocomplementemia, the cellular infiltrate around the vessels contains neutrophils. In normocomplementemic patients, lymphocytes predominate.

Neurovascular disease may be the only manifestation of vasculitis. The two common clinical patterns include a mild distal sensory neuropathy and a severe sensorimotor neuropathy (mononeuritis multiplex).⁸² The latter form is characterized by severe arterial damage on nerve biopsy specimens. Symptoms of the milder form may consist of paresthesias or “burning feet” in association with decreased touch and pin sensation distally. Patients with mononeuritis multiplex have weakness (e.g., footdrop), in addition to sensory abnormalities. Symptoms and signs are identical to those found in polyarteritis nodosa. Rheumatoid pachymeningitis is a rare complication of RA; confined to the dura and pia mater, this process may be limited to certain areas (e.g., lumbar cord, cisternae).⁸³ Elevated levels of IgG (including IgM and IgG RFs and low-molecular-weight IgM) and immune complexes are found in the cerebrospinal fluid.

Visceral lesions occur generally as claudication or infarction of the organ supplied by the involved arteries. Intestinal involvement with vasculitis manifests as abdominal pain, at first intermittent and progressing often to continuous pain and a tender, quiet abdomen on examination. If infarction develops, resection must be accomplished promptly. Gangrene of digits and extremities, intestinal lesions with bleeding or perforation, cardiac or renal involvement, and mononeuritis multiplex indicate extensive vasculitis and are associated with a poor prognosis.⁸⁴

Other entities in the differential diagnosis for rheumatoid vasculitis include diabetes mellitus, infection, atherosclerosis, and drug reactions. Current practice is to treat organ-specific vasculitis aggressively when it occurs in RA patients, similar to treatment for patients with polyarteritis. This therapeutic approach may be responsible for the small excess mortality in rheumatoid vasculitis patients compared with “controls” with RA alone. In 61 patients with rheumatoid vasculitis, after allowance for general risk factors such as age and sex, the mortality risk was only 1.26 times that of rheumatoid patients without vasculitis.⁸⁵

Renal Disease

The kidney is rarely involved directly in RA but often is compromised indirectly by therapy. Amyloidosis is an unusual complication of chronic RA. AA amyloidosis is one of the most important life-threatening complications of RA. Phenacetin abuse causes renal papillary necrosis; salicylates and other NSAIDs may cause abnormalities as well. Membranous nephropathy is related to therapy with gold salts and penicillamine and was seen when these agents were commonly used to treat RA. Rarely, a focal necrotizing glomerulitis is seen in patients dying with RA and disseminated vasculitis.

Pulmonary Disease

Pleural Disease

Pleuritis is commonly found on autopsy of patients with RA, but clinical disease during life is seen less frequently. In about 20% of patients, pleuritis develops concurrently with the onset of arthritis. Pleuritic pain is not usually a major complaint. Effusions are exudative and can be large enough to cause dyspnea. Characteristics of exudative rheumatoid effusions include a very low glucose concentration in the range of 10 to 50 mg/dL, protein greater than 4 g/dL, mononuclear cells 100 to 3500/mm³, elevated lactate dehydrogenase, low pH, and depressed total complement activity.

(CH₅₀). The low glucose concentrations are of importance because infection (particularly tuberculosis) is the only other condition in which such a low pleural fluid glucose level is seen. Impaired transport of glucose into the pleural space seems to be the cause of this.⁸⁶

Interstitial Pneumonitis and Fibrosis

Pulmonary fibrosis can occur with some regularity in RA and is associated with increased mortality. Similar to findings in scleroderma, physical findings consist of fine, diffuse, dry rales. Radiographs show a diffuse reticular (interstitial) or reticulonodular pattern in both lung fields; this can progress to a honeycomb appearance on plain radiographs and a characteristic lattice network on high-resolution CT scans. Pathologic findings include diffuse fibrosis in the midst of a mononuclear cell infiltrate. The principal functional defect is impairment of alveolocapillary gas exchange with decreased diffusion capacity, best measured using single-breath carbon monoxide diffusion capacities.⁸⁷ Interstitial lung disease and RF and ACPA positivity can occur in smokers before articular symptoms develop.⁸⁸ This finding has led to the novel hypothesis that RA-specific autoimmunity might be generated in the lung in response to environmental insults such as smoking. Bronchoalveolar lavage may reveal increased numbers of lymphocytes, even in patients with only mildly abnormal chest radiographs and normal pulmonary function test results.⁸⁹ In more aggressive disease, a higher proportion of neutrophils can be found in bronchoalveolar lavage. Lymphoid interstitial pneumonitis has been described in patients with RA and Sjögren's syndrome. This relatively indolent disorder is associated with elevated serum globulin levels. Bronchoalveolar lavage shows a primarily lymphocytic response.⁹⁰

Nodular Lung Disease

Pulmonary nodules can appear singly or in clusters that coalesce. Single nodules appear as coin lesions and, when significant peripheral arthritis and nodules are present, can be evaluated by needle biopsy. Caplan's syndrome,⁹¹ in which pneumoconiosis and RA are synergistic, producing a violent fibroblastic reaction with obliterative granulomatous fibrosis, has become a rare occurrence as the respiratory environment in mining operations has improved. Nodules may cavitate, creating a bronchopleural fistula. In several cases, solitary pulmonary nodules in RA patients have proved to be a rheumatoid nodule and a coexistent bronchogenic carcinoma.⁹² If the index of suspicion is high for malignancy, the workup should be more aggressive.

Bronchiolitis

An uncommon finding is interstitial pneumonitis that progresses to alveolar involvement and bronchiolitis, respiratory insufficiency, and death. Pathologic studies show a cellular loose fibrosis and a proteinaceous exudate in bronchioles and alveoli; interstitial infiltrations of lymphocytes attest to the immunogenic aspects of the disease. The course and prognosis are similar to those of idiopathic bronchiolitis obliterans with organizing pneumonia.

Pulmonary Hypertension

Pulmonary hypertension is more common in RA than was previously appreciated. Noninvasive echocardiograms have suggested that mild pulmonary hypertension can be detected in more than 30% of patients with RA.⁹³ Most of these patients are asymptomatic and do not have significant progression.

Small Airways Disease

Defined by a reduced maximal midexpiratory flow rate and maximal expiratory flow rate at 50% of functional vital capacity, small airways disease was observed in 50% of 30 RA patients compared with 22% of a control population.⁹⁴ The study was adjusted for pulmonary infection, α 1-antitrypsin deficiency, penicillamine treatment, environmental pollution, and smoking. Other investigations have not found small airways dysfunction in RA and have suggested that, if present, it probably is related to factors other than RA.⁹⁵ If real, this phenomenon may be part of a generalized exocrinopathic process in the disease, expressed most commonly in Sjögren's syndrome.

Pulmonary Disease due to Treatment of Rheumatoid Arthritis

Many of the drugs used to treat RA are associated with pulmonary toxicity. For instance, methotrexate and leflunomide can cause pulmonary fibrosis in a pattern that resembles RA. Differentiating rheumatoid pulmonary fibrosis from drug-induced fibrosis can be difficult, and this uncertainty might require discontinuing methotrexate therapy in some cases. An idiosyncratic form of methotrexate pulmonary toxicity is less common and usually is accompanied by fever, lung infiltrates, and eosinophilia. Treatment with TNF inhibitors can lead to reactivation of pulmonary or extrapulmonary tuberculosis.

Cardiovascular System

Cardiac disease in RA can take many forms. It has become apparent that increased risk of premature death in RA is due largely to an increased incidence of cardiovascular disease, primarily myocardial infarction and congestive heart failure. Advances in echocardiography have made the diagnosis of pericarditis with endocardial inflammation easier and more specific. Myocardial biopsy through vascular catheters has facilitated diagnosis and classification of myocarditis. In a detailed study of rheumatoid patients using echocardiography, Holter monitors, and electrocardiography, it was reported that 70% of patients with nodular disease and 40% of those with non-nodular RA have some cardiac involvement, including valve thickening or incompetence.⁹⁶

Atherosclerosis

Multiple risk factors for coronary artery disease in RA patients are known, in addition to the risk factors that are relevant in the general population. Patients with prolonged RA have a greater extent of atherosclerosis than patients of

the same age with more recent disease onset.⁹⁷ Many of the same risk factors noted in RA patients have been implicated in patients without rheumatic diseases, including molecules involved in the immune response, markers of inflammation, and therapeutic agents. It is apparent that, with all else being equal, tobacco smoking is an important factor in augmenting early atherosclerosis in RA patients.⁹⁸ In a large, well-studied population of rheumatoid patients at the Mayo Clinic, patients were followed until death, migration from Olmsted County, or 2001. Data show that congestive heart failure was more important than ischemic heart disease as a cause of death.⁹⁹ Even in RA patients without clinically evident cardiovascular disease, left ventricular diastolic function and right ventricular diastolic function are reduced.¹⁰⁰

Pericarditis

Infrequently diagnosed on the basis of history and physical examination in RA, pericarditis is present in 50% of patients at autopsy. In one study, 31% of patients with RA had echocardiographic evidence of pericardial effusion. The same study revealed only rare evidence of impaired left ventricular function in prospectively studied outpatients with RA.¹⁰¹ Although unusual, cardiac tamponade and/or the more common constrictive pericarditis can develop in RA and may require pericardiectomy. Almost all patients have a positive test for RF, and half have nodules. Preservation of good ventricular function on echocardiography in the face of deteriorating clinical myocardial function should raise a high index of suspicion of constrictive pericarditis.

Myocarditis

Myocarditis is rare but may be due to granulomatous disease or interstitial myocarditis. The granulomatous process resembles subcutaneous nodules and could be considered specific for the disease. Diffuse infiltration of the myocardium by mononuclear cells may involve the entire myocardium and yet may have no clinical manifestations, but it could be suggested by echocardiography.

Endocardial Inflammation

Echocardiographic studies have reported evidence of previously unrecognized mitral valve disease of the anterior leaflet of the mitral valve. Although aortic valve disease and arthritis are more commonly associated with ankylosing spondylitis, numerous patients with granulomatous nodules on the valve have been reported.¹⁰²

Conduction Defects

Atrioventricular block is unusual in RA but is probably related to direct granulomatous involvement. Pathologic examination may reveal proliferative lesions or healed scars. Complete heart block has been described in more than 30 patients with RA. It generally occurs in patients with established erosive nodular disease.¹⁰³ Complete heart block usually is permanent and is caused by rheumatoid granulomas in or near the atrioventricular node or bundle of His. Rarely, amyloidosis is responsible for heart block.

Granulomatous Aortitis or Valvular Disease

In severe rheumatoid heart disease, granulomatous disease can spread to involve even the base of the aorta. Occasionally, granulomatous disease associated with RA necessitates urgent valve replacement for aortic regurgitation.¹⁰⁴ With improved therapy for synovitis, these complications (similar to many others) have become rare.

DIAGNOSIS

Criteria to establish the diagnosis of RA are based on an effective clinical history and physical examination, laboratory tests, and exclusion of other diagnoses. No single feature or laboratory test is sufficient for a definitive diagnosis. The 1987 American College of Rheumatology (ACR) criteria for classification usually are not used for diagnosis in individual cases; however, the requirement that objective evidence of synovitis must be present for at least 6 weeks is important, especially because many transient forms of synovitis are observed in primary care settings (Table 70-3). A physician would be less likely to make a premature diagnosis of RA in a patient who might have a self-limited synovitis. To attempt preventing irreversible damage to joints, the diagnosis of RA should be confirmed or ruled out within 2 months after the onset of synovitis.

Classification criteria were revised in 2010 by the ACR and the European League Against Rheumatism (EULAR).¹⁰⁵ The new criteria place greater emphasis on serology and early diagnosis in patients with very few or even no swollen or tender joints (Table 70-4). Symmetric joint disease is not a feature of the new criteria. In addition, classic radiographic changes such as marginal erosions automatically qualify patients for RA classification if they have a single swollen joint. Imaging evidence of synovitis, including ultrasound or MRI, can be used to classify patients even in the absence of symptoms if patients have high titers of RF or ACPA and elevated acute phase reactants. The long-term usefulness and the specificity of the classification of the revised criteria are uncertain, but their use will likely result in earlier diagnosis and treatment. It is important to recognize that these are not diagnostic criteria, and they are used mainly in classifying patients for clinical research.

The characteristic patient with RA reports pain and stiffness in multiple joints, with prominent and prolonged morning stiffness. Joint swelling is boggy and includes soft tissue and synovial fluid. Joints are tender, especially the small joints of the hands and feet, but usually are not painful when the patient is at rest. Palmar erythema and prominent veins on the dorsum of the hand and wrist indicate increased blood flow. DIP joints are rarely involved. The temperature over the involved joints (except the hip) can be elevated, but the joints usually are not red. The range of motion is limited, and muscle strength and function around inflamed joints are diminished. Soft, poorly delineated subcutaneous nodules are often found in the olecranon bursa. Findings on general physical examination are normal except for a possible low-grade fever in a few patients. Soft, small lymph nodes are found occasionally in epitrochlear, axillary, and cervical areas. The history and physical examination are the

Table 70-3 1987 Revised American Rheumatism Association Criteria for Classification of Rheumatoid Arthritis*

Criterion	Definition
Morning stiffness	Morning stiffness in and around the joints lasting at least 1 hour before maximal improvement
Arthritis of ≥ 3 joint areas	At least 3 joint areas simultaneously having soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician (the 14 possible joint areas are [right or left] PIP, MCP, wrist, elbow, knee, ankle, and MTP joints)
Arthritis of hand joints	At least 1 joint area swollen as above in wrist, MCP, or PIP joint
Symmetric arthritis	Simultaneous involvement of the same joint areas (as in criterion 2) on both sides of the body (bilateral involvement of PIP, MCP, or MTP joints is acceptable without absolute symmetry)
Rheumatoid nodules	Subcutaneous nodules over bony prominences or extensor surfaces, or in juxta-articular regions, as observed by a physician
Serum rheumatoid factor	Demonstration of abnormal amounts of serum rheumatoid factor by any method that has been positive
Radiographic changes	Changes typical of RA on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized to or most marked adjacent to involved joints (osteoarthritis changes alone do not qualify)

American College of Rheumatology Criteria	Sensitivity (%)	Specificity (%)
Morning stiffness	68	65
Arthritis in >3 areas	80	43
Arthritis of the hand joints	81	46
Symmetric arthritis	77	37
Rheumatoid nodules	3	100
Rheumatoid factor	59	93
Radiographic change	22	98

Clinical or Laboratory Variable	Persistent Nonerosive Versus Self-Limiting		Persistent Erosive Versus Persistent Nonerosive	
	Odds Ratio	Score	Odds Ratio	Score
Symptom duration at first visit				
>6 weeks, <6 months	2.49	2	0.96	0
>6 months	5.49	3	1.44	0
Morning stiffness >1 hour	1.96	1	1.96	1
Arthritis in ≥ 3 joints	1.73	1	1.73	1
Bilateral MTP compression pain	1.65	1	3.78	2

Anticitrullinated protein antibody positivity	4.58	3	4.58	3
Radiographic erosions (hands or feet)	2.75	2	Infinite	Infinite

*For classification purposes, a patient is said to have RA if he or she has satisfied at least four of the seven criteria. Criteria 1 through 4 must be present for at least 6 weeks. Patients with two clinical diagnoses are not excluded. Designation as classic, definite, or probable RA is not to be made.

MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal; RA, rheumatoid arthritis.

most sensitive and specific tools for diagnosis of RA. Initial laboratory tests often show the results in the following list (essential tests are indicated with an asterisk [*]):

- Normal white blood cell count and differential*
 - Thrombocytosis*
 - Mild anemia, normochromic and either normocytic or microcytic*
 - Normal urinalysis*
 - ESR 30 mm/hr or greater and C-reactive protein level greater than 0.7 pg/mL*
 - Normal renal, hepatic, and metabolic tests*
 - Normal serum uric acid level
 - Positive RF test (about 70% to 80% of patients; occurs in many normal people, in patients with other rheumatic diseases, and in those with chronic infection)*
 - ACPA (about 80% to 90% of patients; can be seen in other diseases, including active tuberculosis) (especially useful as diagnostic and prognostic indicator of early synovitis)*
 - Other autoantibodies (commonly found but with limited differential diagnosis utility, including anti-nuclear antibody, SS-A, and SS-B). Although they usually are not clinically indicated, tests for anti-double-stranded DNA and antineutrophil cytoplasmic antibody are usually negative.
 - Polyclonal gammopathy as determined by serum protein electrophoresis
 - Normal or elevated serum complement level
- “Typical” arthrocentesis, when obvious fluid is present, in RA reveals the following:
- Joint fluid is straw-colored, is slightly cloudy, and contains many flecks of fibrin and 5000 to 25,000 white blood cells/mm³; at least 50% of these are polymorphonuclear leukocytes.
 - No crystals
 - Complement C4 and C2 levels are depressed, but C3 level can be normal.
 - Normal synovial fluid glucose level
 - Negative cultures and Gram stain

Table 70-4 2010 ACR/EULAR Classification Criteria for Rheumatoid Arthritis (Score-Based Algorithm for Classification in an Eligible Patient [Cutpoint for RA: $\geq 6/10$])

Joint Involvement*	(0-5)
1 medium to large [†] joint	0
2-10 medium to large joints	1
1-3 small [‡] joints (with or without involvement of large joints)	2
4-10 small joints (with or without involvement of large joints)	3
>10 joints [§] (at least one small joint)	5
Serology [*]	(0-3)
Negative RF AND negative ACPA	0
Low-positive RF OR low-positive ACPA	2
High-positive RF OR high-positive ACPA	3
Acute Phase Reactants [*]	1
Normal CRP AND normal ESR	0
Abnormal CRP OR abnormal ESR	1
Duration of Symptoms**	(0-1)
<6 weeks	0
≥ 6 weeks	1

*Joint involvement refers to any swollen or tender joint on examination, or evidence of synovitis on magnetic resonance imaging or ultrasonography. Distal interphalangeal joints, first carpometacarpal joint, and first metatarsophalangeal joint are excluded from assessment. Categories of joint distribution are classified according to the locations and numbers of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

[†]Medium to large joints refer to shoulders, elbows, hips, knees, and ankles.

[‡]Small joints refer to the metacarpophalangeal joints, proximal interphalangeal joints, metatarsophalangeal joints 2 through 5, thumb interphalangeal joints, and wrists.

[§]In this category, at least one of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular).

^{||}Individuals should be scored by these criteria only if at least one serologic test and at least one acute phase reactant test result are available. Where a value for a serologic test of acute phase reactant is not available, that test should be considered as negative/normal.

*Negative refers to international unit (IU) values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to IU values that are greater than the ULN but less than or equal to 3 \times ULN for the laboratory and assay; high-positive refers to IU values that are greater than 3 \times ULN for the laboratory and assay. Where RF is available only as positive or negative, a positive result should be scored as low-positive for RF.

#Normal/abnormal is determined by local laboratory standards.

**Duration of symptoms refers to patient self-report of the duration or signs or symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment.

ACPA, anticitrullinated protein/peptide antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor; ULN, upper limit of normal.

Differential Diagnosis

Other diseases must be excluded before the diagnosis of RA is established.¹⁰⁶ The differential diagnosis of adult polyarthritis is outlined in Table 70-5.¹⁰⁷ The following sections lists various diseases; the relative frequency of each illness is specified as common, uncommon, or rare.

Spondyloarthropathies (Common)

Ankylosing spondylitis, psoriatic arthritis, inflammatory bowel disease–associated arthritis, and reactive arthritis are often referred to as *spondyloarthropathies*. These diseases generally are marked by their respective nonarticular features and the following pattern of joint disease: asymmetric, oligoarticular, lower extremities more than upper extremities, and large joints more than small joints (note that there are

Table 70-5 Discriminating Features in Patients Presenting with Polyarthritis and Fever

Symptom or Sign	Possible Diagnoses
Temperature $>40^{\circ}$ C	Still's disease Bacterial arthritis SLE
Fever preceding arthritis	Viral arthritis Lyme disease Reactive arthritis Still's disease Bacterial endocarditis
Migratory arthritis	Rheumatic fever Gonococcemia Meningococcemia Viral arthritis SLE Acute leukemia Whipple's disease
Effusion disproportionately greater than pain	Tuberculous arthritis Bacterial endocarditis Inflammatory bowel disease Giant cell arteritis Lyme disease
Pain disproportionately greater than effusion	Rheumatic fever Familial Mediterranean fever Acute leukemia Acquired immunodeficiency syndrome
Positive test for rheumatoid factor	Rheumatoid arthritis Viral arthritis Tuberculous arthritis Bacterial endocarditis SLE Sarcoidosis
Morning stiffness	Systemic vasculitis Rheumatoid arthritis Polymyalgia rheumatica Still's disease Some viral and reactive arthritides
Symmetric small joint synovitis	Rheumatoid arthritis SLE Viral arthritis
Leukocytosis ($>15,000/\text{mm}^3$)	Bacterial arthritis Bacterial endocarditis Still's disease Systemic vasculitis Acute leukemia
Leukopenia	SLE Viral arthritis
Episodic recurrences	Lyme disease Crystal-induced arthritis Inflammatory bowel disease Whipple's disease Mediterranean fever Still's disease SLE

SLE, systemic lupus erythematosus.

many exceptions to these general guidelines). The problem in differentiating these diseases from RA arises with a patient (particularly a woman) who has minimal back pain and definite peripheral joint involvement. The presence of low back pain and lumbar involvement helps distinguish these diseases from RA.

In distinguishing patients with reactive arthritis from those with RA, a careful search for heel pain or tenderness and ocular or urethral symptoms is of great importance. Polyarthritis persists chronically in more than 80% of patients with reactive arthritis. The characteristics of enthesopathy in patients with reactive arthritis (i.e., “sausage” digits indicating periarticular soft tissue inflammation, insertional tendinitis, periostitis, and peri-insertional osteoporosis or erosion) may point to the diagnosis.

The differential diagnosis between RA with psoriasis and some forms of psoriatic arthritis may be artificial (see Chapter 43). Some patients with DIP joint involvement and severe skin involvement have a disease that is not RA. Others have a seropositive symmetric polyarthritis that appears to be RA, yet they also have psoriasis. These patients can be treated with the same disease-modifying drugs that are given to patients with progressive RA, including TNF inhibitors.

As a syndrome described extensively in the French literature, synovitis, acne, pustulosis, hyperostosis, osteitis (SAPHO)¹⁰⁸ may resemble psoriatic arthritis and, occasionally, when peripheral arthritis is present, RA. As the name implies, patients variably have severe acne, palmar and plantar pustules, hyperostotic reactions (particularly in the clavicles and sternum), sacroiliitis, and peripheral inflammatory arthritis.

Inflammatory bowel disease (ulcerative colitis and Crohn’s disease) is associated with arthritis in 20% of cases (see Chapter 78). Peripheral arthritis occurs more commonly than spondylitis in many series.¹⁰⁹ Ankles, knees, and elbows are the most typically involved peripheral joints, with PIP joints and wrists next in frequency. Simultaneous attacks of arthritis and the development of erythema nodosum are common. Only two or three joints are affected at once. Involvement is usually asymmetric, and erosions are uncommon. The occurrence of peripheral arthritis in inflammatory bowel disease is not related to HLA-B27.

Behçet’s syndrome is marked by asymmetric polyarthritis in 50% to 60% of cases (see Chapter 93).¹¹⁰ It is rare, with a prevalence of less than 1 in 25,000 in the United States. In more than half of cases, the attacks of arthritis are monoarticular. Knees, ankles, and wrists are affected most often; synovial fluid usually contains more than 5000 but less than 30,000 white blood cells/mm³. Joint deformity is unusual. Painful oral and genital ulcers and central nervous system involvement are characteristic. Uveal tract involvement in Behçet’s syndrome must be differentiated from the scleritis characteristic of RA in patients with ocular and joint disease.

Enteric infections are complicated occasionally by inflammatory joint disease resembling RA. The joint disease associated with *Yersinia enterocolitica* infection occurs several weeks after the gastrointestinal illness. Knees and ankles are the joints most commonly involved, and most patients

(even patients with peripheral arthritis and no spondylitis) have HLA-B27. Reactive arthritis also has been reported after *Salmonella*, *Shigella*, and *Campylobacter* (*Helicobacter jejuni* infection).

Calcium Pyrophosphate Dihydrate Deposition Disease (Common)

Calcium pyrophosphate dihydrate deposition disease is a crystal-induced synovitis that takes many forms, ranging from a syndrome of indolent osteoarthritis to that of an acute, hot joint. About 5% of patients have chronic polyarthritis (sometimes referred to as pseudo-RA) associated with proliferative erosion of subchondral bone. Although radiographs are helpful when chondrocalcinosis is present, calcium pyrophosphate dihydrate deposition disease may be present in the absence of calcification on radiographs.¹¹¹ Diagnosis then can be made only by arthrocentesis. A radiographic sign of calcium pyrophosphate dihydrate deposition disease that helps to differentiate it from RA is the presence of unicompartamental disease in the wrists (see Chapter 96). On physical examination, the MCPs in calcium pyrophosphate dihydrate deposition disease generally have bony enlargement rather than soft tissue swelling owing to synovial hyperplasia.

Fibromyalgia (Common)

In fibromyalgia, no evidence of synovitis is found (see Chapter 52). Although no specific diagnostic tests define this entity, nonarticular pain and tenderness are common. In an analysis contrasting the pain properties of fibromyalgia versus those of RA,¹¹² fibromyalgia patients used diverse adjectives to describe their pain, the most common being “pressing,” “shooting,” “gnawing,” “cramping,” and “crushing.” Most patients in both groups defined the pain as aching and exhausting. Some patients with diffuse connective tissue diseases, including RA, can develop a superimposed fibromyalgia, adding to the difficulty of treating the arthritis.

Gout (Common)

Before a diagnosis of chronic erosive RA is made, chronic tophaceous gout must be ruled out. The reverse applies as well. Features of gouty arthritis that can mimic the features of RA include polyarthritis, symmetric involvement, fusiform swelling of joints, subcutaneous nodules, and a subacute presentation of attacks. Conversely, certain aspects of RA that suggest gouty arthritis include periarticular nodules and seronegative disease (particularly in men). Radiographic findings may be similar, with the appearance of subcortical erosions of RA resembling small osseous tophi in gout. Although large asymmetric erosions with ballooning of the cortex and overhanging edges are more likely to be caused by gout than by RA, this is not always the case. Serologic test results may be misleading as well; RF has been reported in 30% of patients with chronic tophaceous gout who have no clinical or radiographic signs of RA.¹¹³

Human Immunodeficiency Virus Infection (Common)

Several types of arthropathy have been described in association with human immunodeficiency virus (HIV) infection, including the following¹¹⁴:

- Brief, acute arthralgias concurrent with initial HIV viremia
- HIV-associated arthritis, lower extremity noninflammatory oligoarthritis, or a persistent polyarthritis
- Seronegative spondyloarthropathy resembling psoriatic arthritis, or reactive arthritis, often more severe than in patients without HIV infection¹¹⁵

It is crucial to rule out HIV in any patient with an acute polyarthritis and fever: HIV-positive patients are at greater risk for toxicity or opportunistic infection when using immunosuppressive drugs (see Chapter 114). HIV-positive patients also can present with syndromes of vasculitis.

Infectious Diseases (Including Viral Causes Such As Hepatitis C) (Common)

Arthritis is commonly associated with viral infection and sometimes can mimic RA. For example, symmetric inflammatory arthritis complicates rubella or rubella vaccination more often in adults than in children and may affect the small joints of the hands. Lymphocytes predominate in synovial effusions of rubella.

Rheumatoid-like arthritis often precedes jaundice in viral hepatitis and is associated with the presence of circulating hepatitis B surface antigen and hypocomplementemia. The surface antigen has been found in synovial tissues with the use of direct immunofluorescence; this supports the concept that this synovitis is mediated by immune complexes.¹¹⁶ Acute onset of diffuse polyarthritis with small joint effusions and minimal synovial swelling, often accompanied by urticaria, should prompt the physician to request liver function tests in the patient with a history of exposure to hepatitis. With the onset of icterus, arthritis usually resolves without a trace.

Increasing recognition of hepatitis C as a cause of joint problems is related to the availability of specific serologic tests for this virus. About one-third of people infected with hepatitis C virus have arthralgias or arthritis, and in a Korean series, the prevalence of cryoglobulins (mean concentration of 9.8 g/L) was 59%.¹¹⁷ Patients can present with palmar tenosynovitis, small joint synovitis, carpal tunnel syndrome, and positive tests for RF. The presence of ACPAs can be a useful feature in distinguishing RA from hepatitis C–associated arthritis.¹¹⁸ Other findings, including mixed cryoglobulinemia syndrome, glomerulonephritis, and cutaneous vasculitis, round out the clinical spectrum of rheumatic complaints associated with this viral infection. Because exacerbation of hepatitis can be associated with the use and the cessation of methotrexate therapy, a good case has been made for testing for hepatitis C every patient with RA scheduled to be started on therapy with this drug.¹¹⁹

Fever, sore throat, and cervical adenopathy followed by symmetric polyarthritis are compatible with infection resulting from hepatitis B, rubella, adenovirus type 7, echovirus type 9, *Mycoplasma pneumoniae*, or Epstein-Barr virus

and acute rheumatic fever or adult-onset Still's disease. In Japan, many more patients with RA have circulating antibodies against human T-lymphotropic virus type I (HTLV-I), and epidemiologic evidence indicates that HTLV might be associated with an RA-like condition. Multiple nodules within tendon sheaths associated with inflammation resembling rheumatoid tenosynovitis have been described in a patient with HTLV-I arthropathy.¹²⁰

A chronic polyarthritis resembling RA has been described after serologic proof of parvovirus infection. Usually the process is self-limited and does not progress to a destructive synovitis (see Chapter 114). Adults, often those involved in child care, present with a history of a viral-type illness, sometimes with desquamating finger involvement and a diffuse, red facial rash ("slapped cheeks"), followed by arthralgias and synovitis.

Chikungunya is an insect-borne virus found in Africa and Asia that manifests infection as an acute febrile phase with rash followed by prolonged arthralgia or arthritis of multiple joints. Arthritis usually persists for weeks to months but in some cases can last for years.

Polyarthritis after bacterial infection such as poststreptococcal arthritis also can resemble RA. Typically, patients have an antecedent skin or oropharynx group A streptococcal infection in the weeks preceding symptoms. Antistreptolysin O antibody titers are usually elevated. Although the same bacteria can cause glomerulonephritis, it is uncommon to see concomitant arthritis and renal disease.

Lyme Disease (Common in Endemic Areas)

Lyme disease can closely simulate RA in adults or children because of its intermittent course with the development of chronic synovitis. A proliferative, erosive synovitis necessitating synovectomy has evolved in several cases. The histopathologic appearance of the proliferative synovium is not different from that of RA (see Chapter 110), and the Lyme synovial cells produce a similar excess of metalloproteinases. Lyme serologic tests can help distinguish this disease from RA, as can a history of tick bites, characteristic skin rash, or neurologic involvement.

Osteoarthritis (Common)

Although osteoarthritis can begin as a degenerative cartilage disease, and RA begins as synovial inflammation, these diseases can overlap as they progress (Table 70-6). In osteoarthritis, as cartilage deteriorates and joint congruence is altered and stressed, a reactive synovitis often develops. Conversely, because the rheumatoid pannus erodes cartilage, secondary osteoarthritic changes in bone and cartilage occur. In osteoarthritis, involvement of the DIP and first carpometacarpal (CMC) joints is common, but it is rare in RA. Alternatively, MCP and wrist involvement are uncommon in OA. During end stages of degenerative joint disease and RA, involved joints appear the same. In some cases, to differentiate clearly between the two, the physician must delve into the early history and functional abnormalities associated with the disease.

Erosive osteoarthritis occurs frequently in middle-aged women (more frequently than in men) and is characterized

Table 70-6 Factors Useful for Differentiating Early Rheumatoid Arthritis from Osteoarthritis

	Rheumatoid Arthritis	Osteoarthritis
Age at onset	Childhood and adults, peak incidence in 50s	Increases with age
Predisposing factors	Susceptibility epitopes (HLA-DR4, HLA-DR1) PTPN22, PADI4 polymorphisms, and others Smoking	Trauma Congenital abnormalities (e.g., shallow acetabulum)
Early symptoms	Morning stiffness	Pain increases through the day and with use
Joints involved	Metacarpophalangeal joints, wrists, proximal interphalangeal joints most often; distal interphalangeal joints almost never	Distal interphalangeal joints (Heberden's nodes), weight-bearing joints (hips, knees)
Physical findings	Soft tissue swelling, warmth	Bony osteophytes, minimal soft tissue swelling early
Radiologic findings	Periarticular osteopenia, marginal erosions	Subchondral sclerosis, osteophytes
Laboratory findings	Increased C-reactive protein, rheumatoid factor, anticitrullinated protein antibody, anemia, leukocytosis	Normal

by inflammatory changes in PIP joints with destruction and functional ankylosis of the joints. The PIP joints can be red and hot, yet almost no synovial proliferation or effusion occurs; joint swelling involves hard, bony tissue, not synovium. The ESR may be slightly elevated, but RF is not found (see Chapter 99).

Polymyalgia Rheumatica and Giant Cell Arteritis (Common)

Joint radionuclide imaging studies demonstrate increased vascular flow in the synovium of patients with classic polymyalgia rheumatica. Clinical synovitis commonly occurs, but markedly symptomatic arthritis is uncommon. A careful history usually can differentiate shoulder or hip-girdle muscle pain from shoulder or hip joint pain. Examination of synovial biopsy specimens from patients with polymyalgia rheumatica indicates that the synovitis is usually milder than that found in RA.

Several patients have been described whose initial symptom of giant cell arteritis was a peripheral polyarthritis clinically indistinguishable from RA.¹²¹ Among 19 such patients in a group of 522 with biopsy-proven giant cell arteritis, however, only 3 were RF positive. The interval between onsets of each set of symptoms was 3 years or less in 15 of the 19 patients; this suggests a relationship between the two (see Chapter 88). It is known that patients with giant cell arteritis often have HLA-DR4 alleles.

Systemic Lupus Erythematosus (Common)

The distribution of involved joints and deformities in systemic lupus erythematosus (SLE) can be identical to that seen in RA. In contrast to RA, SLE arthritis usually does not cause cartilage destruction or bone erosion. The deformities are often reducible, sometimes leading to normal hand radiographs, owing to the effect of placing the hand firmly on the film cassette. Serologies (antinuclear antibody, anti-double-stranded DNA) and major organ system involvement usually can distinguish RA from SLE. However, RA and SLE can overlap, suggesting a mixed picture of both diseases, sometimes referred to as “rhus.” The presence of erosive arthritis in SLE patients is associated with ACPAs.¹²² The frequency of erosive arthritis in SLE patients is approximately 10% to 15%, and the subset of SLE patients that are anti-CCP antibody positive are more likely to have erosive

arthritis, suggesting a pathogenic role for the antibody in the formation of erosions.

Musculoskeletal Pain of Thyroid Disease (Common)

In hypothyroidism (see Chapter 121), synovial effusions and synovial thickening can simulate RA.¹²³ The ESR may be elevated because of hypergammaglobulinemia, but C-reactive protein is normal. The joint fluid is noninflammatory and may have increased viscosity. Knees, wrists, hands, and feet are involved most often, and coexisting calcium pyrophosphate dihydrate deposition disease is frequently found. This syndrome should be distinguished from arthralgias and other nonspecific musculoskeletal problems that often accompany hyperthyroidism and hypothyroidism.

The syndrome of thyroid acropachy complicates less than 1% of cases of hyperthyroidism. This syndrome comprises periosteal new bone formation, which may be associated with a low-grade synovitis similar to hypertrophic osteoarthropathy. Patients with coexisting RA and hyperthyroidism have pain from the arthritis that, although impossible to quantify, seems to exceed the pain expected from the degree of inflammation.

Vasculitis (Uncommon)

Patients with a variety of vasculitides can present with inflammatory arthritis; these syndromes are readily distinguished from RA. Many small vessel vasculitides show palpable purpura and are associated with hepatitis C and cryoglobulinemia. Medium vessel forms of vasculitis, such as granulomatosis with polyangiitis, Churg-Strauss syndrome, or microscopic polyangiitis, include major organ system involvement (e.g., reactive airways disease, glomerulonephritis) and are usually antineutrophil cytoplasmic antibody positive. Polyarteritis nodosa, especially in arthritis associated with hepatitis B, usually is distinguished by renovascular hypertension and other systemic symptoms.

Adult-Onset Still's Disease (Uncommon)

Significant fever at the onset of RA is unusual in adults. Later in the course, if vasculitis or serositis is present, or if intense exacerbations of disease occur, low-grade fever is more common. Adult Still's disease, in contrast, usually

manifests with high spiking fevers. Serologic studies (RF and antinuclear antibody) are negative, and patients do not have subcutaneous nodules. Fever patterns in these patients are often quotidian (i.e., reaching normal levels at least once each day). Occasionally, evanescent salmon-colored or pink macules on the trunk and extremities become more prominent when patients are febrile. The cervical spine may be involved, and loss of neck motion may be striking. Approximately 20% of patients with adult-onset Still's disease showed significant functional deterioration from erosive joint disease, similar to RA.¹²⁴

Abnormal liver function tests consistent with hepatitis and severe abdominal pain can be performed and may confound attempts at diagnosis. Liver involvement is observed in most cases and was noted in more than two-thirds of patients in one series¹²⁵; hypergammaglobulinemia is present in more than 60%. Pericarditis and pleural effusions are observed in less than 25% of cases. In contrast to active SLE with nephritis, the serum complement level is normal or high. Serum ferritin levels can be enormously elevated to well beyond levels expected compared with other acute phase reactants in the same individual.¹²⁶ When levels are greater than 10,000 ng/mL, physicians should strongly consider adult Still's disease as the diagnosis rather than RA. The glycosylated form of serum ferritin, usually greater than 50% of the total, is reportedly low (mean, 16%) during active phases and in remission.¹²⁷

Yamaguchi and associates¹²⁸ developed criteria for establishing the diagnosis of adult Still's disease, which, in numerous series, have greater than 90% sensitivity (Table 70-7). After other diseases have been excluded, adult Still's disease should be considered if five criteria (with more than two being major ones) are met. It is unknown yet whether adding hyperferritinemia would increase the specificity of the diagnosis.

Bacterial Endocarditis (Uncommon)

Arthralgias, arthritis, back pain, and myalgias occur in approximately 30% of patients with subacute bacterial endocarditis.¹²⁹ Symptoms typically occur in one or several joints, usually large, proximal ones. This synovitis probably is caused by the deposition of circulating immune complexes. Confusion with RA can occasionally arise because more than half of patients with endocarditis are seropositive for RF. Fever out of proportion to joint findings in the setting of leukocytosis should lead to consideration of infective endocarditis as a diagnostic possibility, even in the absence of a significant heart murmur. Peripheral emboli with digital infarctions may be found, simulating palpable purpura when they occur on the lower legs. Blood cultures

should be obtained in all patients with polyarthritides and significant fever. Embolic phenomena with constitutional symptoms, including arthralgias, can be presenting symptoms of atrial myxoma, but this process usually mimics systemic vasculitis or subacute bacterial endocarditis more than RA.

Hemochromatosis (Uncommon)

The characteristic articular feature of hemochromatosis that is almost diagnostic is firm bony enlargement of the MCP joints, particularly the second and third joints, with associated cystic degenerative disease and large hook-like osteophytes on radiographs and, frequently, chondrocalcinosis. Marginal erosions, juxta-articular osteoporosis, synovial proliferation, and ulnar deviation are not seen in the arthropathy of hemochromatosis but are common in RA. Wrists, shoulders, elbows, hips, and knees are involved less often than the MCP joints. Arthritis leads the list of diagnoses provided to patients to explain their symptoms before the diagnosis of hemochromatosis is decided.¹³¹ In the series by McDonnell and colleagues,¹³¹ patients with symptoms received a diagnosis of hemochromatosis only after the symptoms had been present, on average, for an extended period (10 years) and after they had visited an average of 3.5 physicians (see Chapter 118). Other distinguishing features include the fact that hemochromatosis is more common in males, and that patients generally will be RF and ACPA negative and may have other features of iron overload, including CHF, liver abnormalities, adult-onset diabetes, and hyperpigmentation.

Hemophilic Arthropathy (Uncommon)

A deficiency of factor VIII or, less frequently, factor IX, sufficient to produce clinical bleeding, frequently results in hemarthroses. Iron overload at the joint generates a proliferative synovitis that often leads to joint destruction. Because iron stimulates metalloproteinase production by synovial cells, when feasible, large hemarthroses should be aspirated, and the joint should be immobilized and wrapped well. The clotting abnormality is rarely overlooked, however, and it is unlikely that a diagnosis of RA would be made in the setting of hemophilia A or B (see Chapter 119).

Hyperlipoproteinemia (Uncommon)

Achilles tendinitis and tenosynovitis can be presenting symptoms in familial type II hyperlipoproteinemia and may be accompanied by arthritis. Synovial fluid findings may resemble the findings of mild RA, and tendon xanthomas may be mistaken for rheumatoid nodules or gouty tophi. Conversely, bilateral pseudoxanthomatous rheumatoid nodules have been described. Treatment of hyperlipoproteinemia with statins may cause an acute or subacute muscular syndrome that resembles myositis or polymyalgia rheumatica more than it resembles RA (see Chapter 85).

Hypertrophic Osteoarthropathy (Uncommon)

Hypertrophic osteoarthropathy may present as oligoarthritis involving the knees, ankles, or wrists. However, patients

Table 70-7 Criteria for Diagnosis of Still's Disease

Major Criteria	Minor Criteria
Temperature >39° C for >1 week	Sore throat
Leukocytosis >10,000/mm ³ with >80% PMNs	Lymph node enlargement
Typical rash	Splenomegaly
Arthralgias >2 weeks	Liver dysfunction (high AST/ALT)

ALT, alanine aminotransferase; AST, aspartate aminotransferase; PMNs, polymorphonuclear leukocytes.

generally give a history characteristic of bone pain rather than joint pain. Synovial inflammation accompanies periosteal new bone formation, which is visible on radiographs. Correction of the inciting factor (e.g., cure of pneumonia in a child with cystic fibrosis) is likely to alleviate the synovitis. The synovium is characterized primarily by an increased blood supply and synovial cell proliferation. Little infiltration by mononuclear cells is seen. Pain in the bones that increases when extremities are dependent is characteristic, although it is not always present. If clubbing is not present or is not noticed, this entity may rarely be confused with RA.

Relapsing Seronegative Symmetric Synovitis with Pitting Edema (Uncommon)

Relapsing seronegative symmetric synovitis with pitting edema (RS3PE) is an uncommon syndrome marked by significant pitting edema of the hands with synovial thickening and joint tenderness.¹³² It occurs predominantly in elderly men and is characterized by rapid onset of symmetric synovitis and pitting edema over the involved joints. Edema usually occurs in the hands and ankles overlying involved distal joints. Symptoms rapidly respond to short courses of corticosteroids and can lead to residual abnormalities, including flexion contractures of the wrists and fingers. Patients are RF negative, and increased risk of neoplastic disease has been suggested. A poor response to corticosteroid treatment and the presence of constitutional symptoms have been observed in patients with an underlying malignancy. Patients can evolve into other autoimmune diseases, including seronegative RA. In addition, the syndrome might represent a variant of another disease, such as polymyalgia rheumatica or reflex sympathetic dystrophy, rather than a distinct entity.¹³³

Rheumatic Fever (Uncommon)

Rheumatic fever is much less common in the developed world than it once was, but it still must be considered in adults with polyarthritis. In adults, arthritis is the most prominent clinical finding of rheumatic fever; carditis is less common than in children; and erythema marginatum, subcutaneous nodules, and chorea are rare. The presentation is often that of an additive, symmetric, large joint polyarthritis (involving lower extremities in 85% of patients), developing within 1 week and associated with a severe tenosynovitis. This extremely painful process is often dramatically responsive to salicylates. In contrast to Still's disease in adults, rheumatic fever generally has no remittent or quotidian fevers and shows evidence of antecedent streptococcal infection. It also has a less protracted course than Still's disease. Many similarities have been noted between rheumatic fever in adults and "reactive" postinfectious synovitis developing from *Shigella*, *Salmonella*, *Brucella*, *Neisseria*, or *Yersinia* infection. As rheumatic fever becomes less common, and because penicillin prophylaxis effectively prevents recurrence of the disease, Jaccoud's arthritis (chronic post-rheumatic fever arthritis) is becoming more rare. This entity, described by Bywaters in 1950,¹³⁴ results from severe and repeated bouts of rheumatic fever and synovitis, which stretches joint capsules and produces ulnar deformity of the

hands without erosions. The same deformity can develop in SLE characterized by recurrent synovitis and soft tissue inflammation and in Parkinson's disease. Differentiating rheumatic fever from RA is particularly difficult when subcutaneous nodules are present with rheumatic fever.

Sarcoidosis (Uncommon)

The two most common forms of sarcoid arthritis often can be easily distinguished from RA. In the acute form with erythema nodosum and hilar adenopathy (Löfgren's syndrome), articular problems usually are related to periartthritis affecting large joints of the lower extremities, classically the ankles. Differential diagnosis may be complicated because many of these patients have RF in serum. Joint erosions and proliferative synovitis do not occur in this form of sarcoidosis.

In chronic granulomatous sarcoidosis, cyst-like areas of bone destruction, mottled rarefaction of bone, and a reticular pattern of bone destruction with a lace-like appearance on radiographs may simulate destructive RA. This form of sarcoidosis is often polyarticular, and biopsy of bone or synovium for diagnosis may be essential because often no correlation is noted between joint disease and clinical evidence of sarcoid involvement in other organ systems. Poncet's disease (tuberculous rheumatism) might actually represent granulomatous "idiopathic" arthritis (i.e., sarcoidosis) (see Chapter 117).¹³⁵

Amyloidosis (Uncommon)

Deposits of amyloid can be found in synovial and periarticular tissues and are presumably responsible for the joint problems of some patients. The synovial fluid in amyloid arthropathy is noninflammatory, and particulate material with apple-green fluorescence after Congo red staining may be found in the fluid. Amyloid may cause punched-out bone lesions that rarely can mimic RA erosions. Amyloid formed of β 2-microglobulin is found in the joints of patients with chronic renal failure, usually patients who are on dialysis (see Chapter 116).

Malignancy (Uncommon)

Direct involvement by cancer of the synovium usually manifests as a monoarthritis. Non-Hodgkin's lymphoma can manifest as seronegative polyarthritis, without hepatomegaly or lymphadenopathy. Lymphoma can manifest as a symmetric polyarthritis.¹³⁶ In children, acute lymphocytic leukemia can manifest as a polyarticular arthritis. Paraneoplastic syndromes and others related to direct involvement with cancer can mimic RA and are described in detail later (see Chapter 122).

Multicentric Reticulohistiocytosis (Rare)

Multicentric reticulohistiocytosis causes severe arthritis mutilans with an opera-glass hand (main en lorgnette).¹³⁷ Other causes of arthritis mutilans include RA, psoriatic arthritis, erosive osteoarthritis treated with glucocorticoids, and gout (after tophi are resorbed by treatment with allopurinol). The cell that causes damage to tissues is the

multinucleate lipid-laden histiocyte, which apparently releases degradative enzymes sufficient to destroy connective tissue. These cells in aggregate produce multiple small nodules around joints of the hands.

Pigmented Villonodular Synovitis (Rare)

Pigmented villonodular synovitis is a nonmalignant but proliferative disease of synovial tissue that has many functional characteristics similar to those of RA but usually involves only one joint. The histopathologic appearance is characterized by proliferation of histiocytes, multinucleate giant cells, and hemosiderin- and lipid-laden macrophages. Clinically, this is a painless chronic synovitis (most often of the knee) with joint effusions and greatly thickened synovium. Subchondral bone cysts and cartilage erosion may be associated with bulky tissue. It is unclear whether this condition should be classified as an inflammation or as a neoplasm of the synovium (see Chapter 123).

OUTCOMES

Many difficulties are associated with establishing a change in patterns of RA in different time periods or different communities. The best data suggest that clinical manifestations of the disease and the extent of disability are declining. Epidemiologic studies suggest that the disease is not changing, but that earlier, more effective treatment has diminished morbidity.

Criteria for clinical remission were proposed by ACR/EULAR in 2011.¹³⁸ Remission can be defined as absence of disease, but its application to RA patients has changed over time. With more effective treatment available, stricter criteria have become more important. Definitions vary widely and can mean absence of clinical and radiologic signs of disease while on treatment, or a disease state with minimal or no activity after therapy is withdrawn. A previous composite system using the Disease Activity Score (DAS) is a mathematical method that includes swollen and tender joints, ESR, and patient assessments of global health.¹³⁹ Notably, this criterion does not mean that the patient truly has complete remission with no evidence of synovitis; however, it can be associated with several active joints. ACR criteria from 1981 require absence of joint tenderness, fatigue, joint pain, joint swelling, and morning stiffness, along with a normal ESR. The goal of the ACR/EULAR revised remission criteria was to develop more stringent but achievable criteria for clinical trials. Remission was defined as tender joint count of 1 or less, swollen joint count of 1 or less, C-reactive protein (CRP) of 1 or less, and patient global assessment of 1 or less. In addition, an index-based definition was included as an alternative. Both definitions performed similarly in validation studies. Some controversy still exists regarding whether the goal should be “clinical” or “imaging” remission when ultrasound or MRI evidence of synovitis is considered. The clinical importance of synovitis diagnosed only by imaging in an asymptomatic patient is uncertain.

With increased numbers of effective therapies available, it becomes increasingly important for physicians to be able to determine which patients would be at greatest risk for

progressive destructive disease, and which patients would have a more benign illness that is not erosive and is responsive to moderate intervention. In addition to predicting which patients may or may not develop erosion, it is equally important to identify which patients who already have erosions are more likely to progress rapidly to joint destruction. One study of an inception cohort of patients newly presenting with inflammatory polyarthritis confirmed the fact that although the initial radiographic score is, as expected, a powerful predictor of subsequent radiographic damage, high titers of RF and ACPAs continue to be powerful predictors of deteriorating radiographic damage in subjects receiving conventional therapy.¹⁴⁰ ACPAs (e.g., to fibrinogen, to vimentin, to fibronectin) are more specific for RA than for RF, can appear before disease onset, and are predictive of more aggressive and destructive disease.¹⁴¹ Antimitigated citrullinated vimentin antibodies recognize peptides with amino acid substitutions that most likely occur as the result of somatic mutations in the joint and might be more predictive of radiographic progression compared with standard ACPAs.¹⁴²

Joint erosions and deformity may not be the most important aspects of disease for the patients. In several studies, the Health Assessment Questionnaire has been shown to be an excellent predictor of work disability and mortality,¹⁴³ and its results can be discrepant from damage measured by radiographs.

Mortality

Infection, renal disease, and respiratory failure traditionally have been the primary factors contributing to excess mortality in RA patients, although congestive heart failure, ischemic heart disease, and peripheral atherosclerosis are more correctly identified as the most common cause of excess mortality in RA (see Chapter 36). In addition, disability develops most rapidly during the first 2 years of RA, supporting the current practice of early aggressive therapy.¹⁴⁴ Persistent premature death and potential widening of the mortality gap in RA patients compared with the general population have been attributed to three potential contributing factors.¹⁴⁵ RA patients are at greater risk for multiple comorbid conditions and poorer outcomes after development of these illnesses. In addition, RA patients often do not receive the best preventive care. Last, systemic inflammation and altered immune responses associated with RA tend to increase and hasten comorbidity and mortality.

Careful epidemiologic studies have indicated that cardiovascular disease is the main cause of increased mortality in RA patients.¹⁴⁶ In the Norfolk Arthritis Register, a primary care-based inception cohort, patients who were seropositive for RF died at an excessive rate within the first 7 years of disease resulting from cardiovascular causes (men, 1.34; women, 2.02) compared with controls.¹⁴⁷ This increased incidence of cardiovascular events in RA patients is independent of traditional risk factors, such as age, sex, smoking status, diabetes mellitus, hypercholesterolemia, systolic blood pressure, and body mass index.¹⁴⁸ The generally accepted explanation is that inflammatory cytokines that are produced in excess in RA (e.g., TNF, platelet-derived growth factor) have the capacity to activate endothelial and subendothelial myofibroblasts, and numerous

inflammatory cells are found in atheromatous plaques. Given that nonrheumatoid patients who have higher levels of C-reactive protein than control groups have higher incidences of coronary disease, these data are consistent with hypotheses. Ultrasonography has shown that RA patients have greater thickness of the common carotid and femoral arteries than healthy controls—a finding that was independent of glucocorticoid therapy but was related to the duration and severity of RA.¹⁴⁹ Platelet-derived microparticles, the small vesicles that are released from the plasma membrane when these cells are activated, are elevated in RA in proportion to disease activity.¹⁵⁰ As was noted earlier, the following factors and pathobiologic mechanisms could contribute to atherosclerosis in RA¹⁵¹:

- Immune complex-mediated endothelial damage
- Acute phase reactants (C-reactive protein and serum amyloid A, both of which have proinflammatory activity)
- Inflammatory cytokines
- High expression of endothelial cell leukocyte adhesion molecules
- Medications (e.g., steroids)
- Prothrombotic factors (e.g., increased platelets, fibrinogen, and thromboxane)
- Endothelial cell dysfunction induced by inflammation

Therapies considered for rheumatoid patients must consider the effects on atherogenesis. In patients with an unfavorable vascular profile, these considerations might include supplementation with omega-3 fatty acids in the diet, early use of 3-hydroxy-3-methylglutaryl co-enzyme A reductase inhibitors (statins that, in addition to providing lipid-lowering effects, reduce C-reactive protein), attempts to reduce elevated levels of homocysteine induced by methotrexate, avoidance of cyclosporine, and aggressive weight loss disciplines and smoking cessation programs. The IL-6 receptor antibody tocilizumab suppresses several risk factors for mortality, including inflammation, elevated ESR, and elevated C-reactive protein. It also alters the lipid profile by increasing low-density lipoproteins, albeit with a concomitant increase in high-density lipoproteins to maintain a similar ratio. The ultimate effects on cardiovascular risk factors and mortality are still uncertain under these circumstances.

In addition to cardiovascular causes of death associated with RA are causes of death due to complications (articular and extra-articular) of RA and to side effects of therapy. The probability of death varies directly with the severity of complications. Potentially morbid articular complications include the various forms of atlantoaxial subluxation, cricoarytenoid synovitis, and sepsis of involved joints. Unfortunately, mortality from infection in RA has actually increased approximately fourfold to fivefold on average from reports from 1982 to 2004.⁶⁵ Extra-articular complications directly causing higher mortality include Felty's syndrome, Sjögren's syndrome, pulmonary complications, and diffuse vasculitis.

One of the largest and best documented studies of survival, prognosis, and causes of death in RA was published by Mitchell and associates.¹⁵² In this prospective trial of 805 patients, which included 12 years of observation, 233 patients died during the course of the study, and survivorship was only 50% of that in population controls. Increased mortality associated with RA is impressive and equals that

seen in all patients with Hodgkin's disease, diabetes mellitus, or stroke (age adjusted).

One prediction suggests that tight control of inflammation might decrease cardiovascular and cerebrovascular events and improve survival. Aggressive use of methotrexate can decrease mortality in patients with cardiovascular or noncardiovascular mortality.¹⁵³ Biologic agents such as TNF inhibitors seem to improve survival, especially in women.¹⁵⁴ TNF blockade can potentially exacerbate heart disease, however, and increases mortality in individuals with preexisting congestive heart failure. Longer-term studies are required to assess the impact of new agents such as rituximab and abatacept on mortality (see Chapter 64).

Increased risk for malignancy has been observed in RA, especially with lymphoma. RA patients have a two to three times higher risk of developing Hodgkin's disease, non-Hodgkin's lymphoma, or leukemia compared with the normal population; this is independent of immunosuppressive therapy. Of lymphomas arising in RA, about half are low grade and half are high grade. Most are B cell lymphomas, although it is not clear whether these originate from clonally proliferated lymphocytes associated with RA. Although the relative risk for total cancer in patients with Felty's syndrome is only twofold, the relative risk for non-Hodgkin's lymphoma in this complication of RA is nearly 13-fold¹⁵⁵—similar to that associated with Sjögren's syndrome.

A meta-analysis of malignancy in adult RA patients indicated that the risk of lung cancer is increased 1.5- to 3.5-fold compared with the general population.¹⁵⁶ Interstitial fibrosis might serve as a risk factor for lung carcinoma, particularly the bronchoalveolar variety.¹⁵⁷ In contrast, risks for colorectal and breast cancer were slightly decreased in RA patients. RA patients have demonstrated a consistently reduced risk for cancer of the gastrointestinal tract.¹⁵⁸ NSAIDs could be responsible for lowering the risk for this form of cancer, as supported by evidence that these drugs can diminish the occurrence and numbers of colonic polyps.

Early clinical trials suggested that solid tumors might be enhanced in patients with RA treated with TNF blockers.¹⁵⁹ Similar data in patients with Wegener's granulomatosis suggest that the combination of etanercept and cyclophosphamide can increase the risk for cancer.¹⁶⁰ However, several large registry studies evaluating the effects of TNF inhibitors on cancer rates in RA patients suggest that the oncogenic effect, if it exists, is small.

Variables Related to Outcome

In attempting to sort out the relative roles of disease manifestations, compared with nondisease factors, in generating disability in RA, investigators have proposed hypothetical models to predict disability in RA using demographic, sociocultural, and clinical characteristics of a consecutive cohort of RA patients.¹⁶¹ Although their methods could not be used to explain the dynamics of disability in 41% of cases, disease-related factors explained 33% and nondisease factors (e.g., depression and psychologic status, education) accounted for 26% of the disability. Other studies have emphasized the following disease factors, which correlate with a poorer prognosis and a greater likelihood of joint destruction:

Table 70-8 Activities of Daily Living and Visual Analog Questionnaire (see Supplemental Figures 70-1 to 70-12 on www.expertconsult.com)

A. How often is it PAINFUL for you to:				
	Never	Sometimes	Most of the Time	Always
Dress yourself?	_____	_____	_____	_____
Get into and out of bed?	_____	_____	_____	_____
Lift a cup or glass to your lips?	_____	_____	_____	_____
Walk outdoors on flat ground?	_____	_____	_____	_____
Wash and dry your entire body?	_____	_____	_____	_____
Bend down to pick up clothing from the floor?	_____	_____	_____	_____
Turn faucets on or off?	_____	_____	_____	_____
Get into and out of a car?	_____	_____	_____	_____

B. How much pain have you had in the PAST WEEK? (mark the scale)	
No pain	_____
Pain as bad as it could be	_____
0	100

From Callahan LF, Brooks RH, Summey JA, et al: Quantitative pain assessment for routine care of rheumatoid arthritis patients, using a pain scale based on activities of daily living and a visual analog pain scale, *Arthritis Rheum* 30:630, 1987.

- Positive RF in serum¹⁶²
- Positive ACPA in serum
- Rheumatoid nodules¹⁶³
- Elevated Health Assessment Questionnaire level of disability¹⁶⁴
- Depression¹⁶⁵
- Persistent ESR elevation (serving as a surrogate for disease control)
- Presence of the shared epitope (QKRAA) on class II major histocompatibility genes

Assessment of the Individual Patient

Assessment of disease activity and its progression is different from prognosis. Prognosis extrapolates from a known set of indices (as noted earlier) and the degree of measured activity of disease to prediction of the outcome. Assessment is the accurate evaluation of disease progression over time. Although the indices listed in the previous section are useful as a way to predict outcomes from one-time measurements, use of three or more assessment measures provides the physician with a graph of progression in an individual patient that he or she can try to flatten out by therapy.¹⁶⁶ Whatever assessment index is used, it should be used early in the patient's disease, so that values are recorded before significant loss of function.

For most patients, a self-report questionnaire based on degrees of difficulty in performing activities of daily living correlates well with joint count, radiographic score, acute phase reactants, grip strength, walking time, functional class estimates, and global self-assessment. One useful self-report includes only eight items from the much longer Stanford Health Assessment Questionnaire (Table 70-8).¹⁶⁷ The limitation of this form—failure to detect clinical improvement in patients with few impairments in activities of daily living—may be offset by its acceptability to patients within busy office practices.

In some situations, more comprehensive joint counts are needed. These include points when large changes in drug therapy are about to be instituted, and when patients are to undergo joint reconstruction by orthopedic or hand surgeons. The Thompson index¹⁶⁸ uses a few joints and weights

data from each joint to reflect the joint surface area, giving a better measure of the “burden of synovitis.”

The choice of imaging techniques and measures is important in assessment of the destructive lesions of RA. The inflammatory lesion in RA is reflected reasonably well by heat, pain, swelling, and tenderness. Joint destruction can occur with minimal inflammation, however. MRI and ultrasound provide ways to visualize pannus development and loss of cartilage (see Chapter 58). In each patient, when the diagnosis of RA is reasonably certain, these measures of assessment and estimates of prognosis should be recorded. They should be major determinants of what therapies are instituted (see Chapter 71).

KEY POINTS

Diagnose rheumatoid arthritis (RA) early and initiate disease-modifying antirheumatic drug (DMARD) therapy at the time of diagnosis.

Treat all patients to a disease activity target—remission or low disease activity.

It is not important what therapy patients receive as long as they are treated until they reach the target.

For most patients, methotrexate will be the cornerstone of DMARD therapy.

Many patients will require combinations of DMARDs with or without biologics to achieve the target.

Many effective biologic DMARDs are available—all are more effective with methotrexate.

NSAIDs may provide useful symptom control but are rarely indicated without DMARDs.

Glucocorticoids are rapidly effective for most but have side effects. Therefore, use only with other DMARDs and ideally only as a bridge to effective DMARD therapy.

Aggressively address the ubiquitous comorbidities of RA, especially cardiovascular disease.

The treatment of rheumatoid arthritis (RA) has evolved dramatically over the past 30 years, perhaps more so than any of the rheumatic diseases. The majority of patients newly diagnosed with RA in 2013 can expect to have their disease in remission if treated early by a rheumatologist. This remarkable fact has come about because of a tremendous expansion of the number of disease-modifying antirheumatic drugs (DMARDs) available (Table 71-1), the realization that these drugs can and should be used in combinations,¹⁻³ and the acceptance that all patients should be treated to a target or goal of remission or low disease activity.¹⁻⁴ To put the current situation into perspective and to celebrate how far we have come, a look back on the most immediate history of RA treatment as chronicled in the 30 years of the *Textbook of Rheumatology* (TOR) seems appropriate.

When the first edition of TOR was published in 1981, Dr. Ruddy, the author of the RA treatment chapter, discussed intramuscular gold and penicillamine as the mainstay of RA treatment, hydroxychloroquine (HCQ) was mentioned as a possible option, and cyclophosphamide and azathioprine were discussed as experimental therapies. By 1985 and the second edition of TOR, azathioprine was approved for treatment of RA and cyclosporine and

Treatment of Rheumatoid Arthritis

JAMES R. O'DELL

methotrexate (MTX) appeared in experimental sections along with total lymphoid irradiation. By the fourth edition in 1993, Ted Harris, always ahead of his time, championed early DMARD treatment but suggested starting with the least toxic DMARDs—HCQ and sulfasalazine (SSZ). MTX was recommended only after the failure of HCQ, gold, and penicillamine. By 1997 and the fifth edition, early DMARD therapy was firmly established, MTX had moved to the front of the line of DMARD therapy, and combinations of conventional DMARDs were first prominently mentioned. The sixth edition (2001), authored by Mark Genovese, reflected sweeping changes in the landscape: Combination DMARD therapy was firmly established; leflunomide had become an alternative to MTX; and, most importantly, the biologics etanercept (ETAN) and infliximab had forever changed the landscape. In the immediate predecessor to this edition of TOR (2009), the concept of treating to a target was discussed and our armamentarium of biologics had expanded to three anti-tumor necrosis factor (TNF) agents and two biologics with new mechanisms of action: abatacept and rituximab. Critical features of contemporary therapy of RA as discussed in the ninth edition of TOR include the strategy of treating all patients to the goal of remission or low disease activity and emphasizing treating to target and not the drugs used; the rediscovery of conventional combination DMARDs; the introduction of two new TNF inhibitors and a biologic with yet another mechanism of action (anti-IL-6 receptor), tocilizumab; and highlighting the critical role of comorbidities, particularly cardiovascular disease in RA. In this edition, for the first time a section on tapering or discontinuing therapy in patients who are doing well has been added, which illustrates just how far we have come in the past 30 years.

Despite how far we have come, many challenges remain and include first and foremost identifying markers that predict in a differential fashion who will respond to or have side effects from which treatment and developing methods to allow us to measure the amount of immunosuppression that agents are producing. If the current pace of advance continues, the next few editions of TOR may see discussion of RA remissions off all treatments and even treatment of and perhaps cures for “patients” before they develop symptomatic RA.

This chapter attempts to discuss the broad principles of treatment, the goals of RA therapy, the timing of different therapies, and the strategies of employing the plethora of options now available to achieve the best control of each patient. Most of the drugs are not covered in detail here; please refer to other excellent chapters for specifics on the NSAIDs (Chapter 59), glucocorticoids (Chapter 60), traditional DMARDs (Chapter 61), immunoregulatory drugs

(Chapter 62), and anticytokine therapies or biologics (Chapter 63).

GOAL OF RHEUMATOID ARTHRITIS TREATMENT

It is remarkable that rheumatologists now have more than 19 approved conventional or biologic DMARDs to choose from. However, despite all these terrific DMARD options, **the most important paradigm shift for the treatment of RA has been the realization that patients should be treated early and to a target of low disease activity or remission.**¹⁻⁴ For those outside the rheumatologic community, this seems like stating the obvious—if you have hypertension, hyperlipidemia, or diabetes, patients are of course treated to get the blood pressure, low-density lipoprotein, or Hb_{A1c}, respectively, down to a defined and easily measured goal. The problem in RA has been having valid reproducible measures of disease activity and remission and then routinely measuring and following those in a clinic. Unfortunately, in RA, there is no single examination finding or laboratory test that satisfactorily measures disease activity.

Many measures have been proposed,⁵⁻¹⁰ and all are composite measures that include information derived from some combination of joint examinations, patient and physician assessment of disease activity, patient function, and laboratory measures of inflammation (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]). Recently, the American College of Rheumatology (ACR) has endorsed a list of disease activity measures that have been shown to correlate with outcomes. Table 71-2 is a partial list of some of the better known of these measures. Each of these measures have strengths and weaknesses¹¹; some rely on only data from the patient, some require complete joint counts by clinicians, and some require laboratory tests to measure

inflammation. The busy clinician rarely has time to document more than 60 tender and swollen joints or wait for laboratory test results to make decisions on patients during their visit. Therefore measures that simplify this process as much as possible are being embraced including those that limit the joints counted to 28 (Disease Activity Score 28 [DAS28]), do not require laboratory tests (Clinical Disease Activity Index [CDAI]), or are entirely dependent on patient data Routine Assessment Patient Index ([RAPID]). There is high correlation among these measures, so currently in the clinic **it is very important that disease activity is measured and less important which measure is used.**

Because none of our therapies cure RA, it seems obvious that the next best goal should be remission. The concept of remission as a goal for RA patients is problematic, however. First, a remission definition that is both relevant and practical has been elusive. To be relevant, remission should be highly predictive of the absence of disease progression over time. To be practical, for clinicians, a remission definition should be easy to apply in real time to patients seen in a clinic as discussed earlier with regard to measures of disease activity. Recently, a new definition of remission for use in clinical trials has been developed by ACR and the European League against Rheumatism (EULAR) (Table 71-3).¹² This definition has been rigorously tested against short-term radiologic outcomes in 1- to 2-year randomized controlled trials (RCTs) follow-up. This definition standardizes remission and is therefore a huge step forward for reporting and comparing results across clinical trials.

However, this definition was designed for clinical trials, not clinical care,¹³ where the need to have results of CRPs in real time becomes a problem. Versions of this that do not require laboratory values have been suggested but not fully accepted (e.g., CDAI, Patient Activity Scale). Perhaps more problematic, many believe that remission defined by clinical data alone will always underestimate the amount of low-level disease activity that could be found if synovial biopsies or advanced imaging techniques such as ultrasound (US) or magnetic resonance imaging (MRI) were employed (see Chapter 58). Significant data exists that many and perhaps most RA patients who meet definitions of “remission” have active disease if assessed by US or MRI.¹⁴⁻¹⁶ Indeed, the newly accepted ACR/EULAR definition allows for a swollen joint, which many would argue is not really remission. Another major problem with “remission” is that from currently available data it is not at all clear that remission, regardless of how it is defined, should be the treatment goal for all RA patients. Many patients do well despite low levels of disease activity. This situation may be analogous to the recent studies that show pushing Hb_{A1c} levels below 6.5, which seemed appropriate for diabetic control, was

Table 71-2 Instruments Used to Measure Rheumatoid Arthritis Disease Activity

Instrument	Score Range	Thresholds of Disease Activity			
		Remission	Low	Moderate	High
Disease Activity Score in 28 joints (DAS28)	0-9.4	≤2.6	≤3.2	>3.2 and ≤5.1	>5.1
Simplified Disease Activity Index (SDAI)	0.1-86.0	≤3.3	≤11	>11 and ≤26	>26
Clinical Disease Activity Index (CDAI)	0-76.0	≤2.8	≤10	>10 and ≤22	>22
Rheumatoid Arthritis Disease Activity Index (RADAI)	0-10	≤1.4	<2.2	2.2 and ≤4.9	>4.9
Patient Activity Scale (PAS or PASII)	0-10	≤1.25	<1.9	≥1.9 and ≤5.3	>5.3
Routine Assessment Patient Index Data (RAPID)	0-30	≤1	<6	≥6 and ≤12	>12

Table 71-3 ACR/EULAR Definitions of Remission in Rheumatoid Arthritis Clinical Trials

Boolean-Based Definition
At any time point, patient must satisfy all of the following: Tender joint count $\leq 1^*$ Swollen joint count $\leq 1^*$ C-reactive protein ≤ 1 mg/dL Patient global assessment ≤ 1 (on a 0-10 scale)
Index-Based Definition
At any time point, patient must have a Simplified Disease Activity Index score of ≤ 3.3

*Include 28 joints plus feet and ankles.

ACR/EULAR, American College of Rheumatology/European League against Rheumatism.

associated with increased cardiovascular mortality mainly due to hypoglycemia in patients with prior cardiovascular histories.¹⁷

- When do the risks and considerable expense of some of our RA therapies outweigh the benefits of escalating therapy further?
- Which patient who has improved dramatically but still has two tender or swollen joints needs a third biologic?
- With regard to the previously cited diabetic patients with cardiovascular disease, which RA patients are most at risk if we push too hard for remission?
- Finally, with current therapies, the vast majority of remissions in RA require ongoing treatment with DMARDs, so the concept of a true remission, meaning one where no therapy is required, remains beyond our current reach for the majority of patients.

Despite the problems defining remission or low-disease activity, it is clear that patients do better if clinicians have a goal. The Tight Intensive Control of RA (TICORA) study¹⁸ was the first to convincingly demonstrate this in a randomized fashion. TICORA was a Scottish study in which patients with less than 5 years of disease were randomized to receive either routine care or to receive intensive care. Both groups were treated with an algorithm of conventional DMARDs (Figure 71-1A). The routine care group had regular follow-up and monitoring, while the intensive group was seen monthly and had proscribed escalation of therapy (protocolized) if they had not achieved the goal of low disease activity (defined in this study as DAS ≤ 2.4). Both groups improved significantly, but the group that was treated to a target (intensive group) did significantly better with mean DAS scores ($=1.6$) in the remission range at 18 months (Figure 71-1B). In the intensive group, 71% achieved an American College of Rheumatology 70% improvement criteria response (ACR70) compared with 18% in the routine care group ($P < .0001$). Further, this clinical improvement translated to significantly less radiographic progression of erosions compared with the routine group (0.5 vs. 3.0; $P = .002$). Importantly, this improved disease control was not associated with an increase in treatment-associated adverse events. Finally, despite more frequent visits, intensive therapy resulted in cost savings

even in the short term. These results were particularly remarkable considering they were obtained using conventional DMARDs alone (see Figure 71-1A) without the use of biologics. Findings from other studies have corroborated these findings.¹⁹⁻²¹ Further, a meta-analysis of tight control²² suggested that tight control strategies work best if protocolized, as was done in TICORA.

Although the TICORA investigators selected low disease activity as the target, the target could have been remission as discussed earlier. Most of the previously endorsed measures of disease activity have defined levels that signify “remission” (see Table 71-2). Predictably, the harder we push for remission with increasing numbers and doses of DMARDs, both conventional and biologic, the more toxicity and the expense (Table 71-4) of our treatments become a concern. Both the ACR and EULAR guidelines, as well as recent reviews,^{1,4} currently state that low disease activity or remission is the goal, and they leave the decision on which one is most appropriate for each unique patient’s situation to the clinician. Therefore until further data elucidate this question, clinicians will need to continue to practice the art and science of medicine when selecting the most appropriate target for each patient.

A RANDOMIZED CONTROLLED TRIAL OF TIGHT CONTROL OF RHEUMATOID ARTHRITIS (TICORA)

Intensive therapy: Goal of DAS < 2.4

CLASSES OF DRUGS

DMARDs: Methotrexate, Sulfasalazine, Hydroxychloroquine, and Leflunomide

The definition of a DMARD is one that has the ability to change (for the better) the course of RA. The most rigorous application of this definition requires RCTs that show not only the ability to change the clinical course of the disease but also the ability to decrease or halt the radiographic progression. By this definition, all of the 10 conventional DMARDs and the 9 biologic DMARDs listed in Table 71-1 qualify with the possible exception of minocycline and HCQ, where only weak evidence exists for radiographic benefits. With the DMARDs listed in Table 71-1 and using these drugs individually or in combinations of two, three, or four as is often done, there are 2569 possible combinations for each individual patient, assuming that biologics are not used in combinations with each other. Obviously, this huge number of choices is both good and bad news for the clinician; it is great to have all the options but impossible to keep them all straight. Therefore to employ these effectively, the clinician must have goals, strategies, and an up-to-date knowledge of the drugs and their interactions and toxicities.

The most widely used conventional DMARDs—MTX, SSZ, HCQ, and leflunomide (LEF)—are discussed in detail in Chapter 61. Together, these four DMARDs along with glucocorticoids (see Chapter 60) currently account for the vast majority of conventional DMARD use. Although less commonly used, gold (both intramuscular [IM] and oral), azathioprine, cyclosporine, and the tetracyclines (minocycline and doxycycline), which are not covered elsewhere in the book, are therefore discussed as follows. Penicillamine is of historical interest²³ but is rarely used and is not discussed in this chapter.

Biologic DMARDs

The biologic DMARDs are discussed in detail in Chapter 63. Within this class of agents we now have the ability to inhibit multiple inflammatory cytokines including TNF (with three monoclonal antibodies (infliximab, adalimumab, and golimumab); the TNF receptor protein

(ETAN); and the pegylated Fab fragment certolizumab, interleukin-1 (IL-1) with the IL-1 receptor antagonist (anakinra), IL-6 (monoclonal antibody to the IL-6 receptor tocilizumab) or to kill or inhibit cell lines important in inflammation including B cells (rituximab) and T cells (abatacept). **It is an understatement to say biologics have changed the landscape of RA therapy forever** both in terms of therapeutic expectations and understanding of RA pathogenesis. Because of their often quick onset of action, particularly with the TNF inhibitors, and their ability to retard radiographic progress, they are increasingly used earlier and more often in RA. The challenge for clinicians is to appropriately integrate conventional and biologic therapies and to use biologics when necessary but to make sure the much less expensive conventional therapies have been maximized.

Glucocorticoids

Glucocorticoids, discussed in detail in Chapter 60, have a long and storied history in the treatment of RA. RA was selected as the first disease to be treated with “compound E” at the Mayo Clinic in 1948.²⁴ Responses were both rapid and dramatic; an analysis of the first 14 patients treated revealed that 100% improved their ESRs by more than 50% within 1 to 3 months, with 80% improving ESRs by at least 70% (an ESR70—a convenient ACR70). Several landmark studies have proven not only clinical efficacy²⁵⁻³⁰ but also the significant radiographic efficacy of glucocorticoids.^{28,30} The recent COBRA trial^{29,30} and the COBRA arm of the BeSt study (discussed later^{19,20}) again demonstrated the significant clinical and radiographic benefit that glucocorticoids can provide. Despite the rapid onset and all the other positive benefits of glucocorticoids in RA, their toxicities are also legend. Currently glucocorticoids are most often and most appropriately used along with DMARDs as part of initial “induction” therapy to get RA patients under control rapidly and then aggressively tapered as the slower-acting DMARDs start to kick in. Historically, the belief has been that once an RA patient was on glucocorticoids, he or she would never get off. This is clearly not true with the effective DMARDs now available—successful tapering is the rule.^{19,20,31} If a patient cannot be successfully tapered off or at least tapered to an “acceptable” low dose, it is a strong indication that the current DMARD program is not working. Long-term use of doses equivalent to prednisone of greater than 7.5 to 10 mg per day is a clear indication that DMARD therapy needs to be escalated. **Importantly, glucocorticoids should almost never be used in RA without DMARDs.**

Other Conventional DMARDs

Gold Salts

Gold injections have been used in the treatment of RA for close to a century—initially intramuscularly and, more recently, orally. With the advent of newer agents, gold is rarely used in most parts of the world. IM gold is a difficult and cumbersome therapy. It is initiated with weekly IM injections, usually starting with 10 mg the first week, 25 mg the second week, and then 50 mg thereafter, until a response is seen, generally between 3 and 6 months. Once the desired

efficacy is seen, the IM injections can eventually be monthly. Frequent monitoring with complete blood counts (CBCs) and urine for protein is necessary. Significant toxicities can occur and include skin rashes, bone marrow depression, and nephrotic syndrome. As problematic as gold treatment is, there is a wealth of evidence that IM gold therapy is beneficial for RA including retarding radiographic progression.³² Some patients, perhaps 10% to 20% of those started on IM gold, will have essentially complete long-term remissions if maintained on injections every 2 to 4 weeks. Of recent interest was a 48-week RCT in patients with active disease despite MTX; the addition of IM gold to MTX resulted in 61% of patients achieving an ACR20 compared with 30% for the MTX + placebo group (Figure 71-2).³³ Despite the known benefits, there is also ample evidence that the two IM compounds, gold sodium thiomalate and gold sodium thioglucose, are being used less by rheumatologists because of the need for meticulous monitoring for serious toxicity and the inconvenience of administration and monitoring.

Auranofin, the gold oral preparation, has been available for more than 20 years but is rarely used. Auranofin has different and less severe toxicity than the IM gold and reportedly less efficacy. Cytopenia and proteinuria are rare, but an enterocolitis with diarrhea leads to intolerance in many. Auranofin is an effective DMARD,³⁴ but RCT data

show that it is less effective than MTX, IM gold, penicillamine, or SSZ.³⁵

Until or unless factors can be found that reliably predict who will get the almost magical clinical response that can be seen with gold, this cumbersome and often difficult-to-manage therapy will continue to disappear. To this end, HLA-DR3 is found in more patients who develop either thrombocytopenia or nephropathy while taking gold injections.³⁶ These data must be balanced against the evidence that human leukocyte antigen (HLA)-DR3 may be associated with a better response to gold therapy, which corroborates a long-time belief shared by many clinicians that those patients who get rashes on gold are often destined to have excellent clinical responses.

IMMUNOSUPPRESSIVE AGENTS

Azathioprine

Azathioprine (AZA), 50 to 200 mg/day, has been used to treat RA for almost 50 years. Because it has been generic for many years, little recent research has been done. Although clearly not a first-line DMARD in contemporary RA treatment, AZA is most commonly used as a substitute for MTX when there are contraindications or intolerance to MTX. This most commonly arises in patients with the

Figure 71-2 Blind trials of therapies in patients with active disease despite methotrexate (MTX). ACR20, American College of Rheumatology 20% composite improvement; CSA, cyclosporine A; HCQ, hydroxychloroquine; SSZ, sulfasalazine.

so-called “MTX flu,” but other situations including pregnancy, liver disease, and renal disease may be indications for AZA in RA. Azathioprine is usually used in combination with other conventional or biologic DMARDs. McCarty and co-workers, who was one of the pioneers of combination therapy in RA, has reported on the combination of MTX, AZA, and HCQ in 69 patients treated in an open-label fashion.³⁷ With this combination, 45% of patients reached remission by the old ACR criteria³⁸ and this combination was well-tolerated.

Neutropenia is the most common complication of AZA treatment. Neutropenia can be predicted with a genetic test for polymorphisms of the enzyme thiopurine methyltransferase (TMPT). Patients who are homozygous for the mutant polymorphism that is nonfunctional (1 in 300 or 0.3% of patients) are sensitive to bone marrow and other toxicities of AZA. Patients who are heterozygotes (perhaps 10% of the population) may have milder neutropenia.³⁹ Unfortunately, this test is expensive. In some centers it may cost up to \$1000 and is not always reimbursed. Some clinicians elect to start with low doses of 50 mg/day and check CBCs at 2 weeks and then increase the dose as needed if the white blood cell (WBC) count is normal. It has been speculated that the subset of patients with the nonfunctional polymorphisms could be the patients who, when AZA was added to a stable MTX regimen, developed an acute febrile toxic reaction characterized by fever, leukocytosis, and a cutaneous leukocytoclastic vasculitis.⁴⁰

Cyclosporine

In the 1990s, cyclosporine (CSA) gained a foothold in the treatment of RA.⁴¹ Cyclosporine, mostly used in transplantation to prevent allograft rejection, inhibits the activation of CD4⁺ helper-inducer T lymphocytes by blocking IL-2 and other T helper type 1 cytokine production⁴² and by inhibiting CD40 ligand expression in T lymphocytes.⁴³ The latter effect prevents T cells from delivering CD40 ligand-dependent signals to B cells. Interest in CSA peaked in the mid-1990s when Tugwell and colleagues⁴⁴ showed that the addition of CSA (2.5 to 5 mg/kg/day) to a stable dose of MTX provided substantial additive benefit over MTX alone. In the CSA + MTX group, ACR20 responses were achieved by 48% compared with 16% for placebo (see Figure 71-2). Additionally, this therapy seemed to slow radiographic progression of erosions.⁴⁵ In this trial, the dose of CSA was decreased if the patient's creatinine level increased to more than 30% of initial values. Unfortunately, follow-up reports on this regimen have revealed that only 22% of patients continued on this combination at 18 months with the most common reasons for discontinuation being hypertension or increasing creatinines.⁴⁵

MINOCYCLINE AND DOXYCYCLINE

Tetracycline and derivatives have a long and somewhat checkered history with regard to the treatment of RA and other arthritides.^{46,47} The mechanism of action of tetracyclines in RA is poorly understood. Tetracyclines are, of course, antibiotics, but additionally they inhibit metalloproteinases, modulate immune responses, and have

anti-inflammatory effects. No evidence indicates that tetracyclines treat the “infection that causes RA” as was touted by some of the original supporters.⁴⁷ However, it is entirely possible that inhibition of nonspecific infections that upregulate the immune response (IL-1, TNF, IL-6) such as periodontitis, bronchitis, and gastritis, to name a few, may be helpful in controlling disease in RA patients. Tetracyclines also have the ability to inhibit biosynthesis and activity of matrix metalloproteinases that have a principal role in degrading articular cartilage in RA. This has been effective in animal models of osteoarthritis (OA) treatment. The presumed mechanism is through chelation of calcium and zinc molecules, which subsequently leads to altered molecular conformations of proenzymes sufficiently to inactivate them.^{48,49} Minocycline has mild but definite inhibitory effects on synovial T cell proliferation and cytokine production and has been shown to upregulate IL-10 production. Further evidence of its ability to modulate the immune system is the fact that it is known to induce anti-DNA-antibody positive lupus in some patients, especially when used to treat acne.

Given in a dose of 100 mg twice daily, moderate statistically significant improvement in clinical parameters of disease activity was found in patients with established RA treated with minocycline compared with placebo.^{50,51} Findings in the treatment of early RA have been more impressive. A study of 46 patients with early rheumatoid factor (RF)-positive RA who had not received previous treatment reported 65% of patients meeting 50% improvement in tender and swollen joints, duration of morning stiffness, and ESR (Paulus criteria), whereas only 13% of the placebo recipients improved similarly over a 6-month period.⁵² In 2001 the results of a 2-year trial comparing minocycline with HCQ were published.³¹ In this small study of patients with early RF-positive RA, the patients treated with minocycline were more likely to achieve an ACR50 (the primary end point) than the patients treated with HCQ (60% vs. 33%) and were more successful in tapering glucocorticoids. This study reconfirms the potential utility of minocycline, particularly in early RF-positive patients.

Although less studied, there is evidence supporting the use of doxycycline in the treatment of RA. In a trial of patients with early RA, doxycycline plus MTX was compared with the use of MTX alone. Investigators studied low-dose doxycycline (20 mg twice a day) and high-dose doxycycline (100 mg twice a day) in combination with MTX and found that both approaches were superior to MTX alone.⁵³ Despite the positive results of this study, replication is necessary.

Potential side effects of tetracyclines include light-headedness, vertigo, rare liver toxicity, drug-induced lupus, and, with longer-term use, cutaneous hyperpigmentation.⁵⁴ Elderly patients appear to be at an increased risk of vertigo. Patients on minocycline have developed lupus-like syndromes, complete with autoantibodies including anti-DNA and occasionally perinuclear antineutrophil cytoplasmic antigen.⁵⁵ Drug-induced lupus has not been reported to develop with doxycycline or with the use of minocycline in patients with RA. The hyperpigmentation can be impressive and may limit treatment in some.⁵⁴ Hyperpigmentation resolves with discontinuation of minocycline and occurs much less commonly if at all with doxycycline.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs including salicylates, covered in detail in Chapter 59, have been a ubiquitous part of RA treatment for more than a century. Over the past several decades as toxicities,⁵⁶⁻⁶¹ particularly gastrointestinal⁵⁶⁻⁵⁸ and cardiovascular, have become apparent^{58,59} and as DMARDs have become better, the use of NSAIDs has fortunately declined. The somewhat surprising cardiovascular toxicities, now known to be strongly associated with not only the cyclooxygenase-2 (COX-2) specific NSAIDs but essentially all NSAIDs, have been particularly concerning with regard to the RA patient populations in which the main excess mortality is largely due to accelerated cardiovascular disease. Like glucocorticoids, **NSAIDs should rarely be used without DMARDs**. Also like glucocorticoids, the goal should be to taper off as soon as possible to avoid gastrointestinal and cardiovascular toxicities.

Treatment Approaches and Strategies

As detailed earlier, the goal of treatment for all RA patients is remission or at least low disease activity; other than toxicity concerns and affordability issues, **clinicians should not care which drug or combination of drugs are used in an individual patient but should focus on getting patients to target with whatever it takes**. There is no magic or correct DMARD or combination of DMARDs that is right for all patients. Each patient presents a unique challenge and comes with unique expectations, biases, disease activity level, damage burden, comorbidities, and insurance coverage issues. One of the most important areas of investigation in RA is to identify parameters that will predict in a differential fashion which patient will respond to which therapy—so far no clear-cut answers that are applicable to the clinical care of the vast majority of patients have emerged. Some have suggested treatment should be different for RA patients with good prognosis versus poor prognosis. This concept is problematic; separating patients into good versus poor prognosis is difficult. Although data suggest certain features are associated with worse prognosis (Table 71-5), unfortunately no data suggest that stratifying our therapies on the basis of prognosis at the individual patient level yields better outcomes. For example, if we could perfectly score prognosis on a scale of 1 to 10, those patients with intermediate scores would conceivably benefit the most from our most aggressive therapies while those with

THE RA WHEEL OF EMPIRIC THERAPY*

*May need to spin more than once for combination therapy!

Figure 71-3 One approach to selecting therapy for rheumatoid arthritis (RA) patients. (Courtesy of James R. O'Dell and Robert Wight, MD.)

low scores do not need them and those with the highest scores may have an unacceptable benefit-to-toxicity ratio. Most patients who meet criteria for classification of RA in clinic and essentially all of those included in clinical trials have poor-prognosis RA with multiple factors listed in Table 71-5. Regardless of the prognostic factors, the goal for each patient is to achieve at least low disease activity. Until or unless parameters are identified, rheumatologists will of necessity continue to use their clinical judgment at the individual patient level.

Without parameters that predict in a differential way response to medications in terms of efficacy or toxicity, one approach to treatment decisions is illustrated in Figure 71-3. Note that several iterations may be required. This figure indicates that we do not have these much-needed parameters and emphasizes that if we hope to treat RA in a rational, scientific way, it is critical to find these parameters. Figure 71-3 also highlights and reinforces the need to include bio-banks with all of our clinical trials. With regard to individual patients, Figure 71-4 (ACR recommendations²) is perhaps a more practical approach. Specific patient populations are discussed as follows.

Table 71-5 Factors Associated with Poor Prognosis in Rheumatoid Arthritis

Presence of rheumatoid factor and titer
Presence of antibodies to anticitrullinated protein antibody and titer
Presence of shared epitope (HLA-DR alleles) and number of copies
Presence of erosive disease at presentation
Disease activity at presentation
Magnitude of erythrocyte sedimentation rate or C-reactive protein elevations
Presence of nodules or other extra-articular features
Female gender
Current and past smoking
Obesity

Treatment of the DMARD-Naïve Patient

The most critically important principle of treating RA effectively is to initiate and rapidly advance DMARD therapy as early as possible. Although this is a universally accepted principle, there is a paucity of rigorous data that directly addresses this point. Few randomized double-blind trials⁶²⁻⁶⁵ in which patients are randomized to early treatment versus late treatment have been conducted, and it is unlikely, not to mention unethical, that any more will be forthcoming. Rather, we accept this foundation principle on the basis of the common and firm belief that treating patients early prevents damage and deformity and preserves

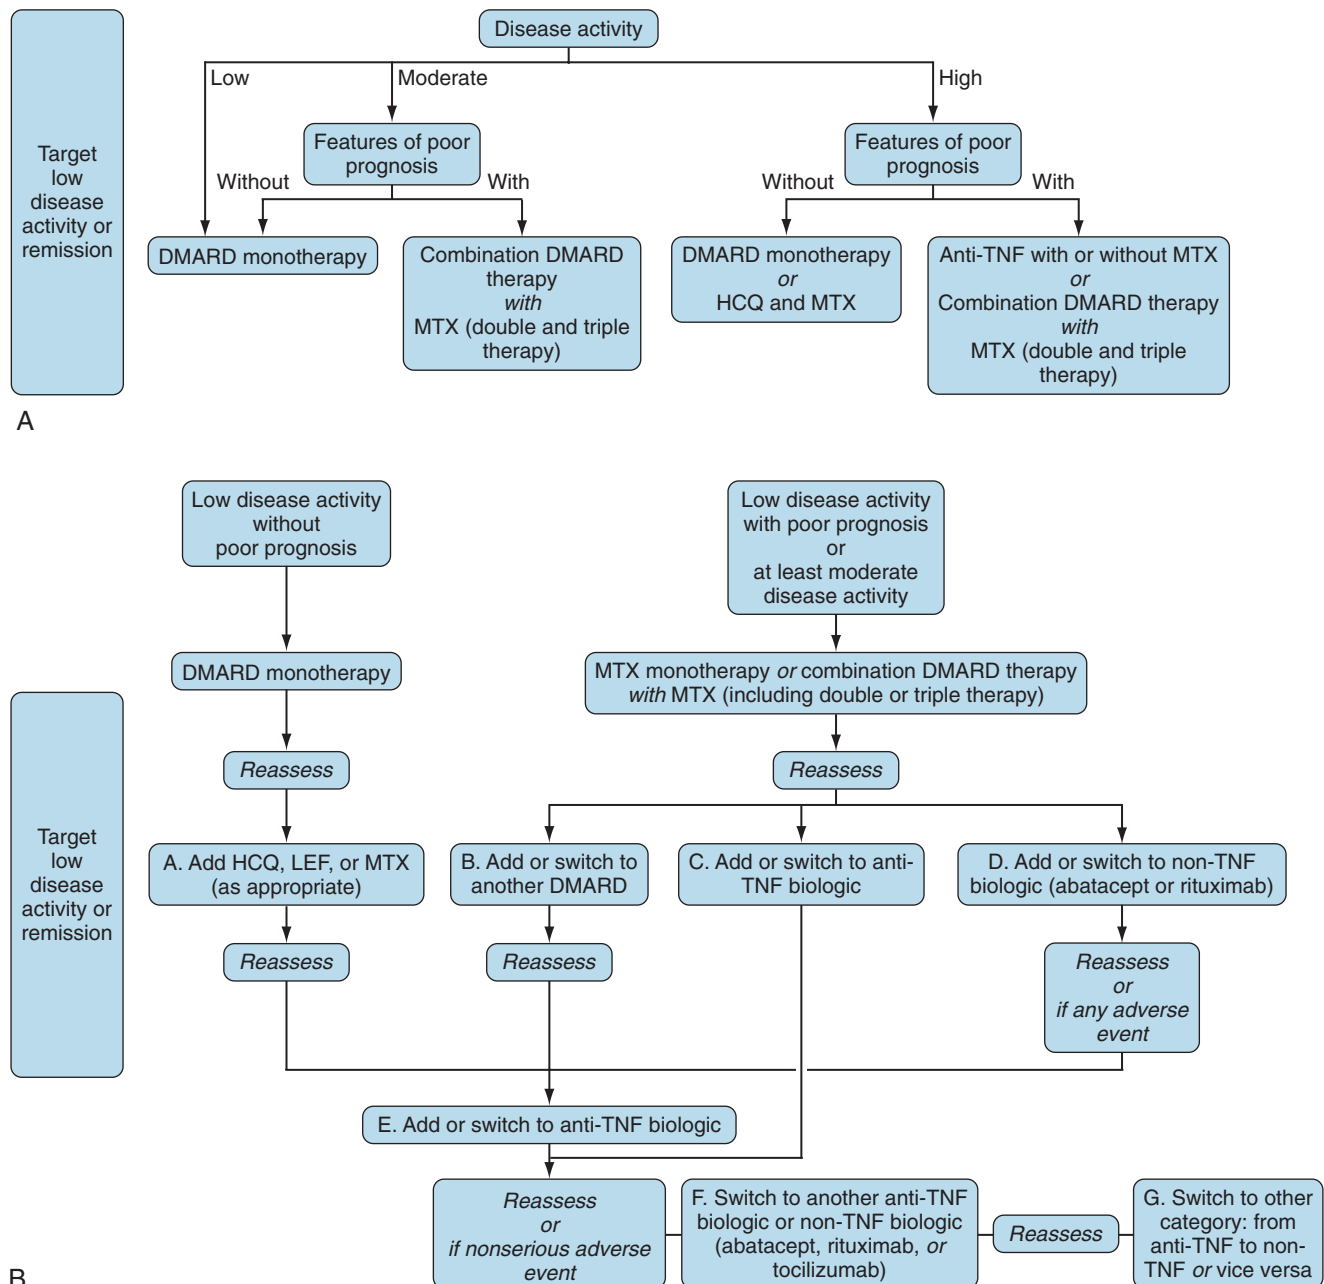

Figure 71-4 American College of Rheumatology recommendations for treatment of rheumatoid arthritis.² **A**, Early disease. **B**, Established disease. DMARD, disease-modifying antirheumatic drug; HCQ, hydroxychloroquine; LEF, leflunomide; MTX, methotrexate; TNF, tumor necrosis factor.

function. Many trials and case series provide strong, credible evidence to support this central tenet. Evidence to support this commonsense belief comes from cohort studies of early versus delayed therapy,⁶⁶ randomized studies of intensive therapy versus usual care,¹⁸ RCTs of combination versus monotherapy,^{19,20,29,67-71} and finally studies of what was previously defined as preclinical RA.⁶⁵

One cohort study of note reported on early RA patients. The first cohort received DMARD therapy early (mean, 123 days after diagnosis), whereas the second cohort received DMARDs very early (mean, 15 days after diagnosis⁶⁶). The first cohort had significantly more radiographic damage at 2 years and, importantly, continued to have radiographic progression while the second did not. The findings of the

TICORA trial (detailed earlier¹⁸) clearly show the advantages of better control of disease earlier. Multiple studies in early RA have demonstrated that when groups of patients are compared, those that get combinations of therapy fare better than those that get monotherapy.^{19,20,29,67-71} COBRA with the combination of MTX, SSZ, and prednisolone versus SSZ alone²⁹; FINRACO⁶⁷ with the combination of MTX, SSZ, HCQ, and prednisone versus SSZ; BeSt with the multiple combinations compared with step-ups or switches^{19,20}; ATTRACT⁶⁹ with the combination of infliximab and MTX versus MTX alone and PREMIER with the combination of adalimumab and MTX versus each alone are some examples of these.⁷⁰ In all these trials, the combinations outperformed monotherapy.

The PROMPT trial⁶⁵ addressed a somewhat different question—patients with inflammatory arthritis who could not yet be classified as RA were randomized to MTX treatment or placebo, and the end point was the development of clinical RA. The MTX-treated group had significantly delayed progression to full-blown RA. Taken together, all these data make a compelling argument for early DMARD therapy in RA.

The new ACR/EULAR RA classification criteria¹² should allow us to classify patients with RA earlier and therefore treat RA patients earlier. The criteria, discussed in detail in Chapter 70, were designed to allow rheumatologists to classify patients in clinical trials with RA as early as possible. Gone is the previous absolute requirement that all patients must have certain features for a minimum of 6 weeks before classification. The 6-week threshold is still acknowledged as important but no longer required, and many patients, particularly those with poor prognostic features, will fulfill criteria before 6 weeks. Importantly, the presence of anticitrullinated protein antibodies (ACPAs), particularly higher-titer antibodies, is weighed heavily in the new criteria (two points). Of note in the previously mentioned PROMPT trial,⁶⁵ the benefit of early MTX was seen only in patients who were ACPA positive. Most, if not all, of these patients in PROMPT would fulfill new criteria for classification as RA, so PROMPT can be thought of as a trial to test the very early treatment of RA versus the delayed approach.

The First DMARD

Accepting that DMARD therapy should be started as early as possible, which DMARD should be started? And should we begin with mono or combination DMARD therapies? Although many of the previously cited studies have shown that combinations outperform monotherapy in randomized controlled trials, this does not mean that initial combination therapy should be the standard approach for all patients in the clinic. Most clinicians initially start most patients on mono-DMARD therapy; the evidence to support this is discussed later and is validated by the recent findings of the Treatment of Early Aggressive Rheumatoid (TEAR) trial.⁷¹ The decision of which DMARD to initiate at the individual patient level is complex, and at this time there is clearly no one right answer for all patients and all clinical situations (see Figure 71-3 or 71-4A)—one size, or in this case one drug, clearly does not fit all. Many factors need to be considered including, but not limited to, the patient's disease activity, comorbidities and preference, the relative expense to the patient and to the health care system (weighing the benefits and including direct and indirect costs in our thinking) and importantly where relevant, the patient's desire (both female and male) to conceive. Until or unless parameters that allow selection on the basis of data become available, this complicated decision will still require the best of the clinician's judgment.

With all this said, MTX should be the initial DMARD for the majority of patients. MTX is inexpensive (see Table 71-4), effective, well-tolerated, and, importantly, is the cornerstone of most successful combination therapies (see Figure 71-2). In particular, excellent data exist that anti-TNF therapy with all the currently available agents is much

more effective with MTX on board both in terms of clinical and radiographic outcomes⁷¹⁻⁷⁴ (see Chapter 61 for specific details on MTX). MTX is usually administered orally at first, although subcutaneous dosing has more predictable bioavailability. In most cases, the dose should be pushed to a minimum of 20 to 25 mg/week if necessary to control disease unless there are contraindications or tolerance problems. Most studies have shown that maximum efficacy may take up to 6 months to achieve but that in most situations, the response at 3 months predicts ultimate success. If MTX is used in this way, approximately 50% of patients will have a good response, and according to consistent data from several trials, approximately 30% will achieve low disease activity status.^{18,19,71,74}

Initiating Treatment with a Single DMARD versus Combinations of DMARDs

Although most clinicians still favor starting with monotherapy, combination DMARD therapy has clearly changed the treatment of RA forever. In the early 1990s, the treatment model called for individual DMARDs and then switching to a different DMARD when necessary. At that time, combinations of DMARDs were not used. Studies published in the mid-1990s showing the impressive efficacy and tolerability of various combinations of DMARDs dramatically changed the treatment paradigm.^{44,75} Now the majority of RA patients are treated with combinations of two, three, or more DMARDs. The first study that put combination DMARD therapy on the map was the so-called *triple therapy study* by the RAIN group of investigators.⁷⁵ This study clearly demonstrated that the triple combination of MTX, HCQ, and SSZ was significantly more effective than MTX alone or the combination of HCQ and SSZ (Figure 71-5). Importantly, this combination of DMARDs did not lead to any increase in toxicity. Multiple publica-

Figure 71-5 Benefits of combination methotrexate/hydroxychloroquine/sulfasalazine (triple) therapy over monotherapy with methotrexate or combination hydroxychloroquine/sulfasalazine. (Adapted from O'Dell J, Haire C, Erikson N, et al: Treatment of rheumatoid arthritis with methotrexate alone, sulfasalazine and hydroxychloroquine, or a combination of all three medications, *N Engl J Med* 334:1287–1291, 1996.)

tions on other successful combinations of conventional DMARDs soon followed.^{29,33,44,67,68,76}

Today, the important question of whether all patients should be started on combinations of DMARDs and then stepped-down or whether started on monotherapy initially and then stepped-up only if patients are not at target is an ongoing debate. Both approaches have their supporters, and data can be presented on both sides of this question. On the one hand, there is no doubt that if short-term responses are looked at in groups of patients, combinations outperform monotherapy. This is true for combinations of conventional DMARDs,^{29,67,68} as well as combinations of conventional DMARDs with a biologic.⁷⁰ On the other hand, the strategy of initial monotherapy with step-ups only in patients who need it was clearly effective in TICORA (as discussed earlier¹⁸) and importantly in the BeSt trial^{19,20} and TEAR trials (discussed later⁷¹), and although initial responses were better in both of the latter trials in the clinical parameters of patients initially treated with combinations, all groups in both BeSt and TEAR had identical DAS or DAS28 scores at the end of 2 years. Clinicians do not treat groups of patients but individual patients, and if the results are similar at 2 years or beyond, effective treatment approaches that minimize the number of DMARDs and therefore their potential toxicities and certain expense will be desirable for patients and health care systems alike.

BeSt (Dutch Acronym for Behandel-Strategieën, "Treatment Strategies") Study

BeSt continues to be an important randomized, multicenter trial in which 508 early RA patients were randomized to receive one of four treatment "strategies" in an open-label study.^{19,20,77} The four arms of the study were as follows:

- **Group 1:** Sequential DMARD monotherapy; initial MTX 15 mg/week → MTX 25 to 30 mg/week → SSZ → Lef → MTX + infliximab → etc.
- **Group 2:** Step-up combination therapy; initial MTX 15 mg/week → MTX 25 to 30 mg/week → MTX + SSZ → MTX + SSZ + HCQ → + MTX + SSZ + HCQ + prednisone → MTX + infliximab → etc.
- **Group 3:** Initial combination therapy; initial MTX 7.5 mg/week + SSZ 2000 mg/day + prednisone 60 mg/day (tapered to 7.5 mg/day by 7 weeks) → MTX 25 to 30 mg/week + SSZ + prednisone → MTX + CSA + prednisone → MTX + infliximab → etc.
- **Group 4:** Initial MTX and infliximab; initial MTX 25 to 30 mg/week + infliximab 3 mg/kg → infliximab 6 mg/kg every 8 weeks → infliximab 7.5 → infliximab 10 mg/kg every 8 weeks → etc.

Treatment adjustments were made every 3 months with the target of a DAS less than or equal to 2.4 (low disease activity). The DAS is calculated using four variables: Ritchie Articular Index (66 tender joint count [RAI]), swollen joint count (44 joints [SJC]), the ESR (mm/hour), and the global health assessment score (0 to 100; [GH]); $DAS = .53938 \times \sqrt{RAI} + .06465 \times (SJC) + .33 \times \ln(ESR) + .00722 \times (GH)$. The major results at 1 and 2 years are shown in Figure 71-6—both combination groups (Groups 3 and 4) improved quicker than Groups 1 and 2, which was expected with high-dose prednisone in Group 3 and high-initial-dose MTX and also infliximab in Group 4. At 1 year, DAS and

other clinical outcomes were similar in all four groups and, importantly, at 2 years they were identical. Health assessment questionnaire (HAQ) scores improved more in the early combination groups (Groups 3 and 4) at 1 year but were not different at 2 years, and radiographic progression at 2 years was greater in Group 1 than in Group 2 and greater in Groups 1 and 2 than in the combination groups (mean modified Sharp van der Heijde Score progression of 9, 5.2, 2.6, and 2.5, respectively). Progression of the joint space narrowing score (importance discussed later), although numerically higher in Group 1, was not statistically different among the four groups (4.3, 2.1, 1.5, 1.2, respectively). Interpretation of these differences is complicated by the fact that despite only 6 months of disease, Group 2 had more radiographic progression at baseline.

Conclusions from BeSt. Treat all patients to a target, and they will all do well, although on many different therapies. It is not so important what patients are on, only that they are at low disease activity or below. Several important caveats apply:

1. The strategy of adding DMARDs as in Group 2 was more effective than the strategy of switching from one DMARD to another, at least for the DMARDs and their order of use in BeSt. Although the clinical outcomes were similar at 2 years for these groups, radiographic progression was greater in Group 1 (mean 9 vs. 5.2), more Group 1 patients required infliximab (26% vs. 6%), and many Group 1 patients ended up on combinations anyway.
2. Initial therapy with combinations of conventional DMARDs (Group 3) or combinations including biologics (Group 4) work more quickly than step-up therapy (Group 2). However, at 2 years, the clinical results were identical. There was a statistical advantage of the combination groups over the step-up group in terms of total radiographic progression (Δ 2.5 points over 2 years); there was no difference in terms of joint space narrowing. This difference in radiographic progression is of no clinical significance unless it continues to grow at similar rates for years. More strategies need to be employed to further change therapies on the basis of radiographic progress in the small group (perhaps 10%) of patients on only conventional therapy where it is relevant.
3. A subset of patients was able to discontinue drug therapy for a period of time. In BeSt, if a DAS score of less than 1.6 was achieved for 6 months, patients were tapered off all medications—this occurred in 115 (23%) of patients. Although many patients relapsed, 59 patients (11.6%) were in remission off all treatment (median follow-up 23 months⁷⁷).

Treatment of Early Aggressive Rheumatoid (TEAR) Trial

The TEAR trial was a landmark study of initial DMARD therapy in patients with early (mean disease duration = 3.6 months), poor-prognosis (all RF positive, CCP positive, or erosive) RA.⁷¹ It is the largest ($n = 755$) investigator-initiated, randomized, double-blind trial in RA to date. TEAR was a 2-year study and sought to address two critical questions in this early RA population:

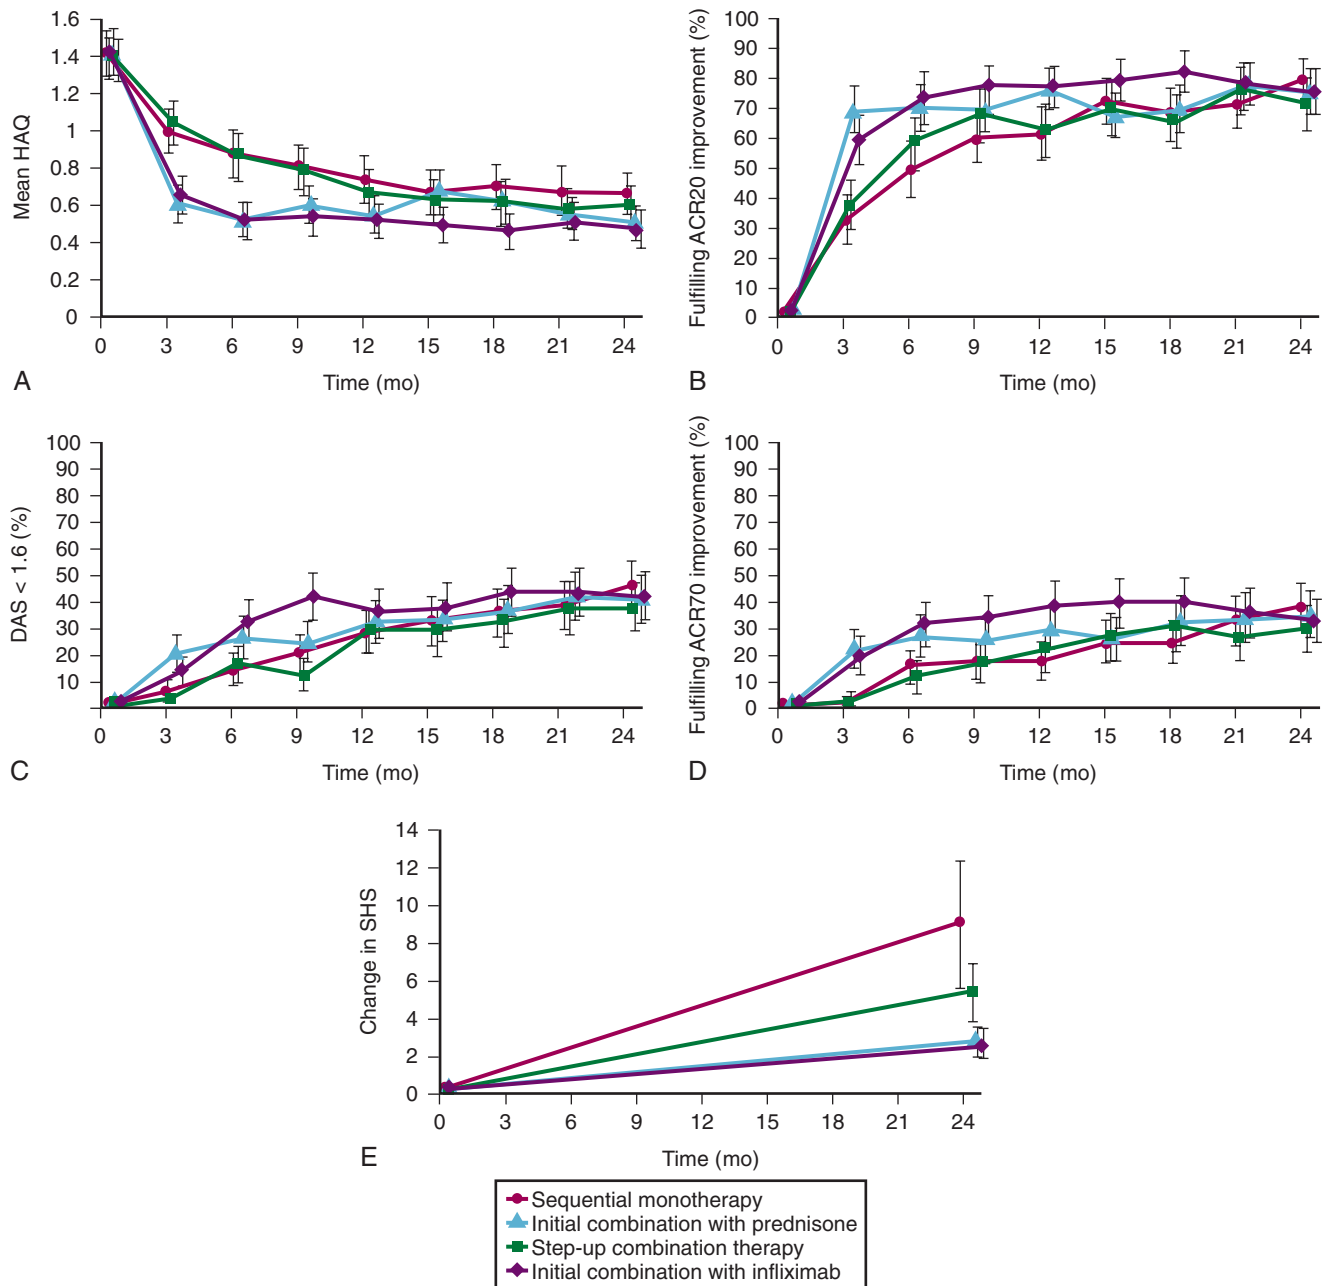

Figure 71-6 A-E, Two-year results of the BeSt study. The error bars indicate 95% confidence intervals. ACR20 indicates American College of Rheumatology 20% composite improvement. DAS, disease activity score; HAQ, health assessment questionnaire; SHS, modified Sharp van der Heijde Score. (Modified from Goekoop-Ruiterman YP, de Vries-Bouwstra JK, Allaart CF, et al: Comparison of treatment strategies in early rheumatoid arthritis: a randomized trial, *Ann Intern Med* 146:406–415, 2007.)

1. Should patients be initiated on combination therapy or stepped-up to combinations only after a trial of MTX monotherapy?
2. Is combination therapy with MTX-ETAN superior to therapy with MTX-SSZ-HCQ (triple) therapy?

The 755 patients were randomized to the four groups as illustrated in Figure 71-7. Randomization was done in a 2:1 ratio with twice as many patients randomized to the ETAN groups. Patients randomized to the MTX-only groups were stepped-up (72% of patients stepped-up) to their assigned combination at 6 months in a blind fashion unless their DAS28 scores were less than 3.2.

The major clinical findings are nicely illustrated in Figure 71-8. All four groups had excellent improvement—mean change in DAS28 equals 2.8. For the primary end point of the study (mean DAS28 between weeks 48 and 102), all four groups were identical. Patients started on combination therapy (either triple or MTX-ETAN) were better than those started on MTX alone at the 6-month point. However, this difference disappeared within 12 weeks of the step-up point and the step-up group's DAS28s were identical to the other groups for the remainder of the study (see Figure 71-8). Data of functional assessments and quality of life measures closely mirrored the DAS28 results. Radiographics

TEAR STUDY SCHEMA

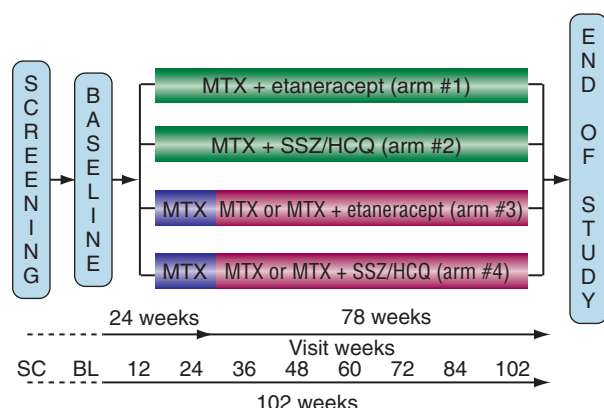

Figure 71-7 Schematic of the four different treatment groups in the TEAR trial.⁷¹ Patients in arms 3 and 4 were treated with methotrexate (MTX) alone and step-up at 24 weeks if DAS28 was greater than 3.2. BL, baseline; HCQ, hydroxychloroquine; SC, screening; SSZ, sulfasalazine.

were done at initiation, at 48 weeks, and at 102 weeks. Radiographic data are presented in Table 71-6, and the cumulative probability plot is shown in Figure 71-9. As shown nicely, the radiographic outcomes of all four groups were superimposable. Table 71-6 shows that there was no difference between the four groups, but if you combine all the ETAN groups and compare them with all the triple therapy groups, the ETAN group had less total modified Sharp score (TSS) progression than the triple therapy group— Δ TSS of 0.51/year ($P = .047$). This small statistical difference was not clinically significant in the 2 years of the

Table 71-6 TEAR Radiographic Results

Treatment Group	N	Δ TSS (over 2 yr)	Standard Deviation
Immediate etanercept	141	0.52	3.24
Immediate triple therapy	74	1.96*	9.48
Step-up etanercept	139	0.76	2.75
Step-up triple therapy	63	1.36	5.00

*One outlier in this group had a Δ TSS of +78.5 points.

No difference between any of the four treatment groups.

No difference between combined immediate therapy versus combined step-up.

Combined etanercept groups had less progression than combined triple therapy ($P = .05$).

If single outlier is removed from triple therapy group, no difference from etanercept ($P = .07$).

TEAR, Treatment of Early Aggressive Rheumatoid; TSS, total modified Sharp score.

trial (see later discussion about interpreting radiographic changes in clinical trials). Importantly, extensive data on side effects revealed no differences between the two groups. Many had speculated that serious adverse events may be more common in the ETAN-treated group, whereas minor toxicities such as gastrointestinal upset and others would be more common in the triple-treated patients—neither was seen in this large, blind, clinical trial.

Conclusions from the TEAR Trial

1. Strategies that initially treat with MTX and step-up to combination therapy only if patients have not achieved target at 6 months are as effective as initial combination therapy in disease control at 1 and 2 years

Figure 71-8 Results of treatment in the four groups of the TEAR trial over 102 weeks. DAS28, disease activity score 28; DMARD, disease-modifying antirheumatic drug; SE, Step-up Etanercept; ST, Step-up Triple. (Modified from Moreland L, O'Dell J, Paulus H, et al: A randomized comparative effectiveness study of oral triple therapy versus etanercept plus methotrexate in early, aggressive rheumatoid arthritis: the TEAR trial, *Arthritis Rheum* 2012, doi 10.1002/art.34498 [Epub ahead of print].)

Figure 71-9 Percentage of patients with radiographic improvement or progression during the 102 weeks of the TEAR trial⁷¹ by treatment group. Measured by total Sharp score. Marks above the line indicate the amount of radiographic progression, while marks below the line indicate improvement. Thus, in this study, less than 10% of patients in any of the four groups had radiographic progression.

with no difference in clinical or radiographic outcomes. At the core of the debate about initial therapy, single DMARD versus combination, is the question of how soon is soon enough when considering control of RA? Is it important to control synovitis and radiographic progression in days or weeks or is control by 3 to 6 months adequate? No clear long-term data exist to answer this important question. In both the TEAR trial and the BeSt study as discussed earlier, the groups treated with combination therapy early did better quicker, but in both trials the step-up groups looked identical to the early combination groups at 2 years in terms of clinical parameters. However, in both studies the early combination groups had small but statistically significantly less radiographic progression at 2 years. In TEAR, this difference was .5 TSS per year and in BeSt it was 1.3 per year.²⁰ Therefore central to this issue is the clinical relevance of small degrees of radiographic progression, which is discussed in detail later.

2. The strategy of using triple therapy was as effective as the combination of MTX-ETAN. This is clearly an important observation and should allow clinicians to be comfortable with this conventional therapy combination. Importantly, and somewhat sobering, the mean DAS28s of the four groups between 1 and 2 years of the trial was around 3.0. This means that almost half the patients were not at target ($\text{DAS28} < 3.2$) regardless of treatment assignment. Therefore in clinical situations, usually after 6 months of therapy these patients should be switched to other therapies to obtain better control of disease. For example, patients on triple therapy are switched to or have ETAN added or MTX-ETAN patients have HCQ and SSZ added. No trial data exist on patients who have failed triple therapy and then are treated with biologics or vice versa.

Treatment of the Patient with Active Disease despite Methotrexate

As discussed earlier, excellent data from clinical trials where patients in general have high disease activity and poor prognostic features show that approximately 30% of patients will achieve a state of low disease activity or better if treated with MTX alone. This figure is consistent across three major trials that documented this response.^{19,20,71,74} Of the 70% that have not achieved this level of control, experience suggests that perhaps a third have improved significantly and either the patient or the physician is not willing to escalate therapy. This still leaves approximately 50% of patients who will need something different than MTX monotherapy. The first question to ask is, “Should patients switch to another DMARD or should other DMARDs be added to MTX?” **Data from multiple sources including BeSt, as discussed earlier, strongly support adding conventional DMARDs or biologics to MTX over switching to another DMARD.**^{19,20,78} A recent trial has nicely addressed the question of stopping MTX versus continuing MTX in patients with active disease who are started on ETAN. This trial randomized 151 patients to either stopping MTX or continuing MTX while starting ETAN. The group that continued MTX fared much better with ACR20s of 86% versus 64% and experienced significantly less radiographic progression as well.⁷⁸

Excellent data now support the efficacy of 15 different clinically available DMARDs or DMARD combinations when added to MTX in this group of patients (active disease despite MTX). This is true for all of the commonly used DMARDs, conventional and biologics alike. **Figure 71-2** highlights the blind clinical trials that have studied currently approved therapies in this patient population.^{25,36,69,79-88} The problem for the clinician is that there is a marked

paucity of data to compare active therapies with each other in this critically important patient population. Knowing that 15 different treatments are better than a placebo is of limited value because most clinicians do not commonly use placebos to treat patients. Therefore trials that compare active therapies are urgently needed.

Two studies shown in [Figure 71-2](#) provide some insight by comparing active therapies to each other in a limited way. In the study by the RAIN group, the combination of SSZ and HCQ appears to be better than either drug alone when added to MTX.⁸² In the study by Schiff and colleagues,⁸⁸ abatacept was numerically better than infliximab for efficacy but this difference did not reach statistical significance. This study has been faulted by some because of the low and fixed dose of infliximab (3 mg/kg every 8 weeks). This is a fair criticism with regard to the efficacy comparison, but importantly, even at this “low dose,” serious and opportunistic infections were increased in the infliximab group compared with the abatacept group. Serious infections occurred in 1.9% of the abatacept and 8.5% of the infliximab group, and all five opportunistic infections in the trial including both cases of tuberculosis occurred in the infliximab group.

The really critical decision for clinicians is whether to add conventional therapies to MTX or take the leap and add biologics. To date, only two studies have addressed this and, unfortunately, both in an indirect way and with different conclusions. An open-label study (SWEFOT) in this population of patients with active disease despite MTX compared adding SSZ and HCQ (triple) to adding infliximab.⁷⁴ At 6 months, both approaches appeared identical with 25% of triple patients and 26% of infliximab and MTX patients responding (EULAR good response); by 1 year, the results were surprisingly different (26% for triple vs. 39% infliximab). It is unclear how these data should be reconciled. One explanation is that infliximab had somehow delayed efficacy with increasing effectiveness between 6 and 12 months. This explanation is problematic because essentially all blind trials have shown that TNF inhibition works quickly and maximum results are achieved by 3 to 6 months. An alternate explanation would be that the open nature of the trial and/or the ability to switch to other therapies affected the perceived responses. Regardless, at 2 years there again was no difference in the number of patients with EULAR good response or the number in remission between these two different approaches.

The second study to address this question, also in an indirect way, was the TEAR trial by Moreland and colleagues as discussed earlier.⁷¹ Although the TEAR trial was designed to look at initial therapy, half of patients initially were treated with MTX alone and are relevant to this discussion. Of these MTX-only patients, 72% or 271 patients did not achieve a DAS28 of less than or equal to 3.2 and were treated with ETAN or the addition of HCQ/SSZ (triple) in a blind fashion. As shown in [Figure 71-8](#), both of these groups looked identical to each other 12 weeks after stepping-up and continued to look identical out to week 102, which was the end of the study. Importantly, with regard to radiographic progression, there was no difference in the radiographic progression of these MTX “failures” in the HCQ/SSZ group versus those in the ETAN group (mean progression of 1.7 vs. 1.1; $P = .57$). Reconciling the

findings of the larger blind TEAR trial with the open Swefot trial is difficult, and further data from blind RCTs designed specifically to address this important question are eagerly awaited.

Until further data are available and despite the problems of comparing data across trials, the clinician will have to base the decision of what to add to MTX in this group of patients on the efficacy data presented in [Figure 71-2](#), the economic information presented in [Table 71-4](#), concerns for toxicity in individual patients, and, importantly, patients’ wishes. This question of course begs for research, and appropriate clinical trials to address this question are urgently needed. However, addressing this question will take several trials because so many therapies with multiple different mechanisms of action (MOA) have been shown to work in this clinical situation (see [Figure 71-2](#)). It would be terrific to be able to select patients on the basis of parameters that suggested which MOA would be most likely to work. Until other data exist, largely because of their long track record, most clinicians favor a TNF inhibitor as the first biologic in this group of patients.

Treatment of “Refractory” Patients or Those with Active Disease despite TNF Inhibition

Despite the effectiveness of conventional DMARD combinations and the TNF inhibitors, a subset of patients will continue to have “unacceptable” levels of disease activity. Estimates of the size of this subset range from 10% to 40% of RA patients. The lack of a universal definition of “refractory” and of “unacceptable” levels of disease activity hampers this discussion. With regard to levels of disease activity, it is clear and probably appropriate that clinicians are willing to tolerate more active disease in this “refractory” group before changing therapy, compared with patients who are naïve to treatment or those treated with active disease despite MTX only. Although clear data are necessary, this approach currently seems prudent as the risk of toxicity and expense of treatment become significant factors.

Increasingly, as our expectations for patients increase, we push to control disease sooner and use biologics earlier and patients are being labeled “refractory” much earlier than ever before. When faced with a “refractory” patient, a close inspection of previous treatments “failed” is in order. It is common for patients to be treated initially with low doses of MTX (≤ 15 mg orally) for 3 months and then started on a TNF inhibitor with or without MTX. If they still have active disease after a few months, patients get labeled inappropriately as “refractory.” It is critical to assess whether MTX therapy has been maximized (see Chapter 61); unless contraindications are present, most patients should have MTX pushed to 25 mg/week and subcutaneous administration should be considered. Data show that triple therapy is as effective as MTX-ETAN,⁷¹ so this combination should be considered when resources are limited before progressing too far down the biologic road.

For patients who are truly refractory, as with the previous section on the patient with active disease despite MTX, we urgently need markers or factors that inform us about the best of many possible approaches. The good news is that we still have multiple options with supportive data even in this difficult patient population, which include switching to

another TNF agent,⁸⁹⁻⁹² starting rituximab,⁹³ starting abatacept⁹⁴ or starting tocilizumab.⁹⁵ Currently there are limited data (discussed later) that direct this choice, so until markers or parameters are available, we will make this decision largely empirically (see Figure 71-3).

TNF inhibition has been around the longest, and because of its efficacy and clinicians' comfort level, many would switch to a second TNF inhibitor before switching to a biologic with a different MOA. A number of observational studies and one RCT support this approach.⁸⁹⁻⁹² From the observational studies, a consistent theme has been that if the first TNF inhibitor was discontinued for toxicity or loss of efficacy, patients have a better chance of efficacy of the second TNF than if the first was discontinued because of primary inefficacy (hazard ratio [HR], 2.7; confidence interval [CI], 2.1 to 3.4⁸⁹). Discontinuation rates, particularly as measured in observational trials, are not the same as efficacy and reflect many things including other treatment options that are available at the time of the study. In the previously cited study published in 2007, golimumab, certolizumab, and tocilizumab were not options.

A single randomized trial has addressed this question of switching to a second TNF inhibitor⁹²; golimumab was given after failure of at least one anti-TNF agent, and 43% responded compared with 17% in the placebo-treated group. A special case in this patient population may be patients who have developed antidrug antibodies. Recently, data have been published with regard to antidrug antibodies in patients treated with adalimumab. After 3 years of treatment, 28% of patients developed antidrug antibodies; in 67% of cases, these developed in the first 6 months.⁹⁶ Development of antidrug antibodies was associated with lack of or loss of efficacy (HR, 3.0; 95% CI, 1.6 to 5.5), and patients were less likely to achieve remission (HR, 7.1; 95% CI, 2.1 to 23.4). Importantly, 38% of patients with antidrug antibodies compared with 14% of those without discontinued therapy for lack of efficacy ($P = .001$). Perhaps of more concern was a recent finding that the development of anti-adalimumab antibodies was associated with thromboembolic events (HR, 7.6; 95% CI, 1.3 to 45.1; $P = .25$ ⁹⁷). These interesting findings raise the possibility that monitoring patients for development of antidrug antibodies not only to adalimumab but also other biologics may be an important strategy to predict not only lack of efficacy but also to prevent toxicities such as thromboembolic events.

Once a clinician decides to go with a biologic with a different MOA, there are currently three choices (although this will likely increase in coming years): rituximab, abatacept, or tocilizumab. Data to help differentiate among them are scarce. On the basis of strong suggestions in the literature that patients who are seronegative for CCP and RF do less well than seropositive patients when treated with rituximab,^{98,99} most clinicians would opt for either abatacept or tocilizumab in the seronegative patient. Randomized trials have shown the efficacy of all three MOAs in this patient population.⁹³⁻⁹⁵ These studies have been similar in design and also in the results of intervention. Patients on MTX with active disease or intolerance to at least one TNF inhibitor have had the TNF inhibitor stopped and are randomized to receive the intervention + MTX or MTX + placebo. Response rates in the three different trials for ACR20 for the active drug versus placebo were rituximab 51% versus

18%,⁹³ abatacept 50% versus 20%,⁹⁴ and tocilizumab 50% versus 10%.⁹⁵ All these responses, however, are less robust than in biologic-naïve patients. On the basis of the strikingly similar response rates of 50% across these three trials, there is little to choose from until further predictors of responses or comparison trial data are available. Some have raised concern about treatment with a second biologic after treatment with rituximab, which depresses B cell numbers significantly for at least 6 to 12 months. Limited data from observational studies provide some reassurance as a significant increase in toxicities has not been reported.¹⁰⁰

What to Do with the Patient in Remission (on DMARDs)

It is a powerful testament of how far therapy for patients with RA has come that it is appropriate to include a new section in this edition on what to do with the patient in remission. It is now common practice for clinicians to ask how to taper DMARDs in patients who are "in remission." Indeed, a recent ACR expert panel acknowledged the importance of this question and included it as one of the top priorities for future investigation.¹⁰¹ Putting aside the obvious difficulty in defining "remission," be it on clinical grounds, with radiographic evidence or by using advanced imaging, clinicians see an increasing number of patients in "remission" or with low levels of disease activity and are increasingly seeking direction on whom should be tapered off of what medications and when.

Unfortunately, again, little data exist. We do not have laboratory tests, inflammatory parameters, or cytokine profiles that help predict who can be safely tapered. Because of their well-chronicled toxicities, the highest priority should be to get all patients off glucocorticoids and NSAIDs. A number of trials^{19,20,31} have shown that with effective DMARD therapy, glucocorticoid tapering is not only possible but should be expected. Perhaps the best example of this is from the BeSt trial in which 92% of Group 3 (the group that got high-dose prednisone up front) was off all prednisone at 2 years.²⁰ In this trial, prednisone was tapered only if the DAS was at or below 2.4 (low level of disease activity).

Once the patient is off glucocorticoids and perhaps on NSAIDs only as needed but still in remission, it is more difficult to know which drug should be tapered next. A common situation is the patient on combination therapy with MTX and a TNF inhibitor. Because of the expense and concerns for long-term toxicities, it would make sense to taper the TNF inhibitor down to the lowest dose possible. Many of these patients in practice may have been started on this combination initially or had the TNF inhibitor added after only a short course of MTX. These patients may be similar to those in the TEAR trial who were started on the combination of MTX-ETAN.⁷¹ For this group of patients we can infer that approximately 30% of them did not need the ETAN and could have done extremely well on MTX alone just as the 28% of patients who started on MTX alone and did not need to step-up. The MTX-only patients who did not step-up not only had the lowest DAS28 at 2 years (mean, 2.7) but also had the least amount of radiographic progression.^{71,102} Unfortunately, we do not know how to select these patients.

If patients have been in remission for 6 months to a year and are being treated with a biologic, it seems prudent to decrease the dose or lengthen the interval between injections. Although most biologics, certainly the subcutaneously administered ones, are dosed in a fixed, one-size-fits-all approach, we know from some of the earlier trials that lower doses than usually clinically prescribed can be effective. As an example, the ERA trial compared doses of ETAN of 10 mg and 25 mg given twice weekly¹⁰³; although the data were slightly better for the higher dose, the low dose clearly had substantial efficacy nearly equal to “full-dose” ETAN, both as measured by clinical (ACR20) and lack of radiographic progression. Therefore a significant percentage of patients may be overdosed, particularly those in remission. In our clinic it is not uncommon to have patients who are in remission taking their 50 mg of ETAN every 2 to 4 weeks or their 40 mg of adalimumab every 3 to 6 weeks.

Although wondering what to do with patients in remission on DMARDs is clearly a wonderful problem to have, further direction is certainly necessary for this emerging and fortunately increasing patient group. Trials to address this question with the collection of biomarkers will be increasingly important as patients continue to do better with current therapies. It is clear that both US and MRI (discussed later) can detect levels of synovitis that are not apparent on clinical examination. As this question is examined further, perhaps we will learn that patients with inflammation by US are not good candidates for discontinuing therapy or, alternatively, US or MRI may provide early warning signs of flares. An interesting recent report indicated that US was able to predict which patients in clinical remission would flare.¹⁰⁴

Use of Combinations of Biologics

Combinations of conventional DMARDs and combinations of conventional DMARDs (especially MTX) with biologics have played a critical role in the vast improvement in responses to treatments we currently see. However, so far efforts to combine biologic products have not met with success. To date, studies to combine ETAN with anakinra have shown no improvement in disease control with ACR50 of 41% in the ETAN-only arm compared with 31% in the combination arm and have shown an increase in serious infections in the combination arm (7.4% vs. 0%¹⁰⁵).

Similarly, in patients with active disease despite ETAN ($n = 80$), patients were randomized to add abatacept or placebo; efficacy showed a nonstatistically significant trend toward improvement (ACR20 for combination, 48% vs. 31%; $P = .07$), but again an increased risk of serious adverse events in the combination group (17% vs. 3%) and serious infections (4% vs. 0%).¹⁰⁶ Finally, a recent small trial ($n = 51$) in which patients with active disease despite MTX and either ETAN or adalimumab were treated with the addition of rituximab or placebo showed modest improvement in efficacy (ACR20 of 30% vs. 17%), and again serious adverse events including infections were numerically greater in the combination-treated group.¹⁰⁷ Despite these less than encouraging results from early biologic combination trials, it is likely that ultimately patients will be treated with combinations of biologics. What is critically needed are good ways to measure the degree of

immune suppression we create with our interventions—a thermostat for TNF, IL-1, or IL-6, if you will.¹⁰⁸ Currently, we are likely inadequately suppressing some patients, therefore not achieving optimal disease control and suppressing others to dangerous levels leading to increased toxicity. When better immune system monitoring techniques are developed, we will be able to better use the biologics we currently have. In addition, it is likely that we will be able to safely and effectively combine biologics to improve outcomes both in terms of efficacy and safety for patients.

Interpreting Radiographic Progression and the Use of Other Imaging Modalities

What is the clinical relevance of radiographic progression? How much progression is significant and over what time period? Are erosions important or should we be concerned only with joint space narrowing? Finally, what role, if any, should US or MRI play in the management of RA?

In clinical trials, treatments of RA are evaluated by clinical parameters (ACR20 responses, DAS, etc.) and radiographic progression (TSS or SHS). This is problematic for a number of reasons. Clinical and radiographic progression is not always parallel. Maybe the most dramatic example of this from an RCT is the PREMIER trial. In the monotherapy arms, MTX alone was significantly better statistically than adalimumab alone, while at the same time, adalimumab alone was better than MTX alone with regard to radiographic progression (Figure 71-10A and B⁷⁰). So which treatment was better? Some would say it is moot because the combination of the two outperformed either monotherapy arm in both measures. However, that misses the point about how to balance radiographic progression versus clinic parameters. Because patients do not come to a clinic complaining of radiographic progression or demanding that it be stopped, the following question is highly relevant: “How is radiographic progression related to things patients do care about—most importantly, physical function?”

Some data relate total Sharp score (TSS) or, similarly, total (SHS) progression to changes on health assessment questionnaires or HAQs (the gold standard for physical function in RA). These data suggest that a change in TSS of 1 equals a change in HAQ of approximately .01.¹⁰⁹ It is well accepted that a clinically significant change in HAQ is approximately .22, so it follows that a change in TSS of 22 is required for a radiographic change to be clinically relevant. This large change is never seen in clinical trials in which active therapies are compared with each other. So although many RCTs have shown statistically significant radiographic progression differences, few if any have shown clinically significant difference within 1 to 2 years of the clinical trial. Additionally, recent data suggest that joint space narrowing correlates well with clinical progression, whereas erosions do not,^{110,111} so perhaps we should not be concerned with TSS but only the joint space narrowing component. The next critically important point is over what duration should we be concerned about radiographic progression? If a trial shows Therapy A results in two less TSS points progression per year compared with Therapy B, it follows that if those same therapies are used for 11 years,

Figure 71-10 Results from the PREMIER trial.⁷⁰ **A**, Clinical improvement measured by American College of Rheumatology 20%, 50%, and 70% composite improvement. **B**, Radiographic progression. ADA, adalimumab; MTX, methotrexate. (Modified from Breedveld FC, Weisman MH, Kavanaugh AF, et al: A multicenter, randomized, double-blind clinical trial of combination therapy with adalimumab plus methotrexate versus methotrexate alone or adalimumab alone in patients with early, aggressive rheumatoid arthritis who had not had previous methotrexate treatment, *Arthritis Rheum* 54:26–37, 2006.)

then patients on Therapy A will have a clinically significant clinical benefit, HAQ .22 less than Therapy B. This is the magnitude of difference (Δ TSS of 1 to 2/year) that has been seen in trials and has led to claims in superiority of one therapy over another. Two problems are readily apparent with this type of extrapolation:

- Within clinical trials patients are often randomized to a therapy and left on it for the duration of the trial regardless of how they are doing. This is not how patients are taken care of in a clinic; if patients are not doing well, therapy is or should be adjusted. Again, the PREMIER trial⁷⁰ is an excellent example of this issue—patients were in their assigned groups for 2 years (see Figure 71-10B). Many were not having optimal clinical response, and therapy would have been changed if similar things were happening in a real-life clinical setting. These patients would not still be in the trial demonstrating their predictable radiographic progression, so in any RCT, radiographic progression that occurs after the time the therapy should have had maximum clinical benefit, and therefore patients would have been switched to a new therapy, is not clinically relevant. In the PREMIER trial, the therapies should have had maximal benefit by 6 months, so if the data after that time point include patients who were not at target (at least low disease activity), then it is not relevant to patients seen in a clinic.
- The second point is similar—to extrapolate forward in the example of a change in TSS of 2/year to 11 years of therapy would only be relevant if all patients were doing well clinically. Patients who are not would have their therapies changed before the two TSS progression per year had a chance to become clinically relevant.

Another major reason why radiographic progression is problematic for the clinician is that formal evaluation of radiographic progression is almost never done outside of clinical trials; few, if any, patients in many countries have formal Sharp score assessment of radiographs. In this regard, routine yearly radiographs in RA are not indicated in many

RA patients and only add to the expense of care. This is true for patients who are not doing well clinically—those patients need a change of care regardless of what the radiographs show, and it is also true for patients who are unwilling or unable to change therapies. The small minority of patients who are at target but who are progressing radiographically are the ones we hope to discover important information with serial radiographs. Finally, the way radiographic information is presented in clinical trials is problematic. Most commonly, the mean TSS progression of Group A is compared with Group B and statistics are done. We are told that Therapy A is superior to Therapy B because there is one or two less TSS progression in that group. A much more informative way to look at radiographic outcomes is to look at cumulative probability plots for radiographic changes (Figure 71-11 for the TEMPO trial^{72,73} and Figure 71-9 earlier for the TEAR trial⁷¹). When data are looked at this way, it is readily appreciated that a small number of patients, perhaps 15% to 20% in the TEMPO trial and in many studies even fewer, are driving

Figure 71-11 Radiographic probability of progression plot from TEMPO.^{72,73}

the radiographic outcome. In the TEAR trial, there are no differences across the four groups in the probability plot. With this epiphany, the important questions are who are these patients and how do we focus on this small group that would benefit from a different therapy and not subject the other 80% to 95% to additional risks and expense? Recently, as mentioned earlier, Aletaha and colleagues¹¹⁰ have called into question the relevance of erosions with regard to clinical correlations and have suggested that joint space narrowing correlates much more strongly with clinical progression. Therefore going forward we need to take this into account.¹¹⁰

Finally, what is the place, if any, of “advanced” imaging techniques in evaluating RA patients? Clearly, both US and MRI are powerful techniques to evaluate early erosions and to detect synovitis (see Chapter 58). One potential use of these obviously sensitive techniques, as suggested earlier, is to verify the true absence of synovitis in patients who are felt to be in remission on clinical grounds.¹⁰⁴ Until further research is available, these techniques will remain largely research tools with regard to routine care of RA patients.

ADJUNCTS TO MEDICATIONS

Patient Education

RA is a lifelong disease, so it only makes sense that patients who are educated about their disease do better, and in fact good data exist to show that education leads to better outcomes.¹¹² Use of the Arthritis Self-Management Program has been shown to lead to less pain, decreased visits to physicians, and economic savings.^{113,114} Chronic diseases such as RA affect the whole family, and participation of spouses in educational group sessions leads to additional beneficial effects.¹¹⁵ Training in stress management is particularly effective in improving measures of helplessness, coping, pain, self-efficacy, and health status.¹¹⁶ Unfortunately, formal education level, a factor that we cannot modify, is associated with morbidity and mortality rates. Formal educational level is inversely proportional to these outcomes, and this cannot be explained by age, duration of disease, joint count, functional measures, or medications.¹¹⁷

Chapter 67 provides an in-depth discussion of many of these important aspects. It is clearly important for patients to take an active role in the management of their chronic disease. The more patients understand their disease and medications, the more control they feel they have over the whole situation. The bond that develops between the patient and physician working together to control this lifelong disease is an important factor in outcome, as well as the satisfaction level of both parties. The stronger the bond is, the less likely that patients will become frustrated and turn to alternative therapies that are not only expensive but may do more harm than good.

Pain Control

If patients with RA are treated early and effectively with DMARDs and therapy is escalated to achieve excellent control of the active components of disease, the need for specific pain medications, particularly narcotics, can be

minimized. If pain is a major problem, the clinician should first review the DMARD program and modify it to achieve maximum control of any active synovitis. Unfortunately, some patients will present in the latter course of disease after substantial joint damage has already occurred and will need pain relief. Pain can be the factor that limits effectiveness of physical and occupational therapy, and as pointed out during a special workshop sponsored by the National Advisory Board for Arthritis and Musculoskeletal and Skin Diseases, it is frequently undertreated in patients with arthritis.¹¹⁸ In addition to inhibiting function, pain is a major cause of depression in patients with polyarthritis. To maximize therapy in patients with early RA or undifferentiated polyarthritis, pain must be controlled without altering consciousness or generating addiction. Treatment strategies favoring education, rest, exercise, and disease-modifying therapies are generally favored as an approach to pain control in arthritis, and strategies that rely on narcotic derivatives may not address control of active RA. In most medical centers, experts in pain management are available for consultation by rheumatologists and primary care physicians (PCPs). There is an excellent discussion of analgesics in rheumatic disease in Chapter 66.

Rest, Exercise, and Activities of Daily Living

Education and supervision of a patient by trained professionals on the importance of finding the best balance of rest and exercise for inflamed joints are essential. This component of therapy can be started well before a definitive diagnosis is made. No matter what the cause, finding this balance should ensure that a patient develops or retains sufficient strength to support joint function without exacerbating inflammation.

Details of physical and occupational therapy are outlined in Chapter 38. A patient with acutely and severely inflamed joints may not be the ideal exercise candidate and may need application of resting splints to immobilize the joint until anti-inflammatory medications, specifically DMARDs, take effect. Even the most painful joints, when splinted, must be moved passively through a full range of motion each day to prevent flexion contractures, particularly in children. For moderately inflamed joints, isometric exercise with muscles contracted in a fixed position (the resting length of the muscle) provides adequate muscle tone without exacerbating joint inflammation and pain. Maximal contractions, held for 6 seconds and repeated 5 to 10 times, performed several times each day, can prevent further loss of muscle mass around arthritic joints.

Patients with well-controlled arthritis will benefit from variable-resistance programs or high-intensity strength training, which has been shown to provide significant improvements in strength, pain, and fatigue levels. Older patients with RA benefit from progressive resistance exercises, similar to younger patients. In a study of older patients given closely regulated workouts on pneumatic resistance equipment, maximal strength of all major exercised muscle groups was increased 75% without exacerbation of clinical disease activity.¹¹⁹ Prescribed sustained exercise not only increases muscle strength but also helps the ability of patients to perform daily routines, improves global assessments and moods, and can decrease pain.¹²⁰

Most patients with RA should have one or more sessions with a licensed occupational therapist (OT) to learn how to preserve joint function and alignment while carrying out the necessary and enjoyable activities of daily living and to be exposed to the assistive devices that are available. The basic concept is to avoid excessive force applied across non-weight-bearing joints and to avoid unnecessary impact loading on weight-bearing joints. A prospective and controlled Canadian trial demonstrated that home therapy by OTs produced a statistically significant and clinically important improvement in function in RA patients.¹²¹

Treatment of Comorbidities and Interaction of Rheumatologist with Primary Care Physician

The best possible outcomes for patients with RA can be achieved only with a carefully orchestrated collaboration between PCPs and rheumatologists. On the one hand, the ever-increasing complexity of RA management options, combination therapies, and possible toxicities of therapy have all made it essential that RA patients are seen by rheumatologists. Good evidence indicates that RA patients are more likely to be on DMARDs, are more likely to be on combination DMARDs, and are happier with their care when seen by rheumatologists.¹²²⁻¹²⁴ On the other hand, the realization of the critical nature of the comorbidities associated with RA, especially cardiovascular disease, makes ongoing engagement of a PCP essential¹²⁵ to produce optimal outcomes.

Significant data indicate that patients with RA have better outcomes when rheumatologists are the primary manager of the RA. In one series of 561 patients with definite RA followed over 20 years, the patients seen by a rheumatologist during the first 2 years of disease fared significantly better than those who did not.¹²⁶ The favorable outcome could be related to an early start of DMARD therapy. Further, data indicate that regular ongoing care by a rheumatologist (mean of 8.6 visits per year) results in less functional disability than for patients who received only intermittent, sporadic care by a rheumatologist.¹²⁷ Analysis of these data supported the interpretation that worsening disability was not the reason for intermittent care, but rather a consequence of it. Additionally, evidence supporting care by a rheumatologist showed that patients who had access to a rheumatologist had higher performance scores than patients who saw only a PCP. Access to specialist care resulted in significant improvements in arthritis care, comorbid illness, and health care maintenance overall beyond seeing a PCP alone.¹²⁸

As important as the rheumatologist is, the PCP needs to be closely engaged (Table 71-7). Recently, the

comorbidities of RA have been highlighted and include premature atherosclerosis and congestive heart failure, increased risks of osteoporosis and fractures, and increased risks of infections. A recent review by a panel of cardiologists and rheumatologists highlighted RA as a significant risk factor for cardiovascular morbidity and mortality on par with diabetes.¹²⁹ In this regard, the PCP needs to aggressively address traditional cardiovascular risk factors such as hypertension and especially hyperlipidemia in RA patients. Statins should be used aggressively because the primary reason for the excess mortality seen in RA is cardiovascular. As an added bonus, statins, probably secondary to their anti-inflammatory effects, have been shown in animal studies of RA models¹³⁰ and in at least one RCT in humans¹³¹ to decrease RA activity. Further, there are data that statin use may protect against the development of RA.¹³²

Because RA and particularly glucocorticoids are risk factors for osteoporosis, the PCP, in concert with the rheumatologist, needs to address this. Most patients should be receiving calcium and adequate vitamin D₃. Bisphosphonates have been shown to prevent steroid-induced osteoporosis,¹³³ and their use should be strongly considered in patients on long-term steroids unless there are contraindications (e.g., women of childbearing age).

With the increased infection risk that RA patients have, both because of their disease and therapies, up-to-date immunizations including yearly influenza shots, every 5-year pneumococcal vaccinations, and appropriate zoster vaccinations are critical.¹ The latter is a live-virus vaccination and should be avoided in patients currently receiving biologics. Current recommendations are to give the zoster vaccination 2 weeks before starting any of the biologics. Influenza and pneumococcal vaccinations can be safely given to patients on biologics with reasonable immunologic response,¹³⁴ except in patients on rituximab, in whom response is severely impaired.^{135,136} The rheumatologist and PCP should push hard for smoking cessation for all the usual reasons plus concern for cardiovascular and pulmonary disease already over-represented in RA; cessation has the added benefit of potentially making patients more responsive to therapies.¹³⁷ Finally, because the PCP often sees the patient first during an illness, the PCP needs to be familiar with the common toxicities of RA medications including concerns about MTX in the patient with decreasing renal function, MTX pneumonitis, and the need for heightened concern and aggressive workup of all potential infections including opportunist infections in immunosuppressed patients, particularly those on biologics. Often, the difference between life and death or at least between excellent outcomes and less than optimal results is the rapidity of response to the early warning signs for things as simple as a cellulitis or a pulmonary infiltrate.

Clearly the best care is given by a team: a rheumatologist, a PCP, and an educated patient all working closely together. Timely consultation with physical and occupational therapists and orthopedic surgeons also plays a role in optimal outcomes for RA patients. Although the need for joint replacement surgery is thankfully decreasing, few interventions have been as successful in improving patient mobility and quality of life as having properly timed hip and knee replacements. With the potential of huge changes in health care delivery on the horizon, at least in the United States,

Table 71-7 Role of Primary Care Physicians in Rheumatoid Arthritis

Monitor and aggressively treat cardiovascular risk factors
Monitor and treat/prevent osteoporosis*
Recognize toxicities of rheumatoid arthritis medications and initiate appropriate and timely workup*
Recognize the risks for infections and ensure immunization status is current

*In partnership with a rheumatologist.

it may be an increasing challenge to assure that the right team is always engaged to achieve the best outcomes for each patient.

Evidence That Patients with Rheumatoid Arthritis Are Doing Better

The prognosis for patients with RA has improved dramatically. Every rheumatologist who has been fortunate enough to see the changes over the past quarter of a century is only too happy to witness to this. The days when wheelchairs were commonplace in clinics and many RA patients had symptomatic C1 subluxations, chronic leg ulcers, constrictive pericarditis, and corneal melts are hopefully gone forever. Despite this firmly held perception by clinicians, strong data to support this change have been slow to accumulate.

Recent data from Olmsted County, Minnesota, show that RA patients diagnosed after 1995 lived significantly longer, almost 9 years, than those diagnosed before 1995.¹³⁸ In the same cohort of patients in Olmsted County, knee surgery was decreased by 46% and hand surgery by 55%.¹³⁹ Data from more than 35,000 U.S. veterans with RA showed a greater than 30% reduction in extra-articular manifestations of RA since the year 2000.¹⁴⁰ Ward, using data from California (years 1983 to 2001), showed that hospitalizations for RA vasculitis or splenectomy for Felty's syndrome decreased by 33% and 71%, respectively.¹⁴¹ Further, primary knee arthroplasty for RA decreased by 10%. Early unpublished reports from many centers indicate that joint replacement surgery for RA may be reduced by up to 50% to 80%. Data from Sweden and Spain¹⁴² both show that disease activity scores and health assessment scores have significantly improved over the past decade.

Investigators postulate it may take up to 20 years for the results of a change in therapy or approach to fully translate into improvement in long-term outcomes such as joint replacements and mortality. Therefore the encouraging data presented earlier likely reflect our therapies of the early to mid-1990s, and therefore we expect that these early reports are the leading wave of good news as some of the therapeutic principles in use for the past decade began to show their full effect.

Research Agenda: Unmet Needs

As mentioned numerous times, huge gaps remain in our knowledge of how to best use the 19 clinically available DMARDs (see Table 71-1) for optimal patient care. At the top of the list of important clinical questions is the urgent need for factors or parameters that would allow us to differentiate the probability of response to or toxicity from different DMARDs at the level of individual patients. This is important for selection of DMARDs for all the categories of patients discussed earlier—DMARD naïve, those with active disease despite MTX, and those who have failed treatment with MTX plus a TNF inhibitor. With regard to specific trials needed in each of these patient groups, a recent ACR task force was formed to prioritize the clinical research trials needed to most expeditiously advance the knowledge base needed to move RA treatment forward.¹⁰¹ After making the strong recommendation that all further

trials include biologic samples to aid in our search for factors that differentiate therapeutic responses, they ordered the trial priorities as follows:

- Trials to elucidate the possible role of induction therapy in early disease
- Treatment of active disease despite MTX and the first TNF inhibitor
- Tapering therapy for patients in remission
- Treatment of active disease despite MTX
- Stratifying patients to determine in advance the most appropriate therapy in order to move beyond the current trial and error approach

Except for studies in patients in remission, the task force emphasized the need for trials that compare active therapies with each other. Further trials that demonstrate the superiority of product X over placebo in any of these areas where multiple treatments have already been shown to work will not provide useful information to clinicians trying to make important clinical decisions. True comparative effectiveness research is necessary to address the multiple options available for patients with RA in all of these categories. Further, the task force stressed the importance of innovative trial designs that more closely mirror clinical practice.¹⁰¹ Examples would include trials that allow escalation or switching of therapies in a blind fashion on the basis of clinical response and not allowing patients with ongoing active disease to continue on fixed therapies after the point of maximal response.

Horizon

It is always difficult to predict the future, particularly in an area where things are changing as rapidly as they are in RA, and certainly the authors of the early editions of TOR could not have predicted we would make the giant strides in RA treatment that we have. As Bill Gates remarked, "We always overestimate the change that will occur in the next 2 years and underestimate the change that will occur in the next 10." By the tenth edition of TOR we will almost certainly have several new biologics and perhaps several new small molecule DMARDs available for treatment. Leading biologic candidates include rilonacept (IL-1 Trap), already approved for cryopyrin-associated periodic syndromes,¹⁴³ and potential targets IL-12,¹⁴⁴ IL-17A,¹⁴⁵ IL-23¹⁴⁶ and IL-33.¹⁴⁷ Prime small molecule DMARDs that inhibit signaling molecules, particular Janus kinases (Jak)¹⁴⁸ and spleen tyrosine kinase (Syk),¹⁴⁹ might become available in the next few years and could dramatically change the treatment paradigm yet again.

Regardless of new therapies that expand our portfolio of choices, the two areas where we will need to see the most progress are profiling patients on the basis of parameters that predict differential responses to different therapies and in monitoring the kinds and intensity of immunologic modification that we are producing. If substantial progress can be made in these areas, even without new therapies, we should be able to obtain vastly superior and more expeditious disease control. On a somewhat more pragmatic note, the treatment of RA has become an expensive endeavor and with all the changes in health care and the continuing increases in the cost, it is imperative that we have the appropriate studies to allow us to take the best care of

patients for the least cost. If we do not have the appropriate research to justify expensive medications, we may have difficulty justifying their use. Therefore it is critical that trials are designed with this in mind and that long-term costs, both direct and indirect, of suboptimally controlled RA be part of the equation.

It is clear from many observations that the immune response that becomes RA starts¹⁵⁰⁻¹⁵² before most patients present with the classic symptom complex. Studies to elucidate this transition are under way¹⁵³ and studies to treat presymptomatic RA are not far behind. Even further, these studies on preclinical disease hold the promise of elucidating the triggers of RA and, if so, the ultimate goal of RA prevention cannot be far behind.

KEY POINTS

Early synovitis refers to synovitis that is detected by physical examination; the symptom duration defining *early* has changed over time.

Intervention in arthritis with symptoms less than 12 weeks can be beneficial and can potentially prevent damage later.

Undifferentiated arthritis (UA) is a diagnosis per exclusion. The phenotypic characteristics and outcome change depending on the classification criteria used for rheumatoid arthritis.

Few clinical trials have been performed in UA, and in none of these studies treatment strategies were adjusted to individual patients' chance on spontaneous remission versus progression to rheumatoid arthritis.

WHAT IS EARLY SYNOVITIS?

Recent data suggest that early therapy and achieving low disease activity improve long-term outcomes in inflammatory arthritis.^{1,2} These observations have increased awareness among rheumatologists of the importance of early diagnosis and treatment. As a result, considerable pathophysiologic research and clinical trials have focused on identifying early synovitis as soon as possible. Stratifying patients into well-characterized diseases, such as rheumatoid arthritis (RA), is essential so that appropriate therapy can be initiated. Equally important, identifying patients with a high chance for spontaneous remission is needed to avoid overtreating individuals with transient undifferentiated synovitis.

Uniform descriptions of patients and accurate diagnostic criteria for early synovitis are essential for proper interpretation of clinical research. At present, no standardized definition for *early synovitis* is widely accepted. In fact, the definition of *early* has evolved over time. Previously, studies used a cutoff of less than 5 years to define early disease for RA. By the 1990s, duration of symptoms for less than 12 to 24 months was considered early. This duration was chosen because most RA patients incur significant damage when treated conventionally.

The window for modifying disease outcomes might be narrow, and maximum benefit might require interventions even earlier; some evidence suggests that treatment within months might be beneficial. For this reason, several early arthritis cohorts in recent years strictly restrict the inclusion criterion of symptom duration and include only patients with a symptom onset of less than 12 weeks; this is referred

Early Synovitis and Early Undifferentiated Arthritis

ANNETTE H.M. VAN DER HELM-VAN MIL •
THOMAS W.J. HUIZINGA

to as *very early synovitis*. Even this definition probably does not capture the earliest phase of disease, as circulating antibodies might appear years before the onset of symptoms in RA, and biomarkers reflecting bone destruction are elevated before arthritis is present.^{3,4} Animal models show that histologic evidence of inflammation and activation of signaling pathways can occur well before clinically apparent disease.

Although the term *synovitis* generally refers to a swollen joint detected by physical examination, alternative definitions are also applied. Physical examination might not be sensitive enough, and clinically undetectable synovitis may be present and relevant to identify. Therefore, some studies consider tenderness in the absence of swollen joints as synovitis. For instance, early arthritis clinics might include patients with tenderness but no swollen joints. Others determine synovitis not by physical examination but through the use of imaging modalities such as ultrasound (US) or magnetic resonance imaging (MRI). Different ultrasound techniques are used; of these, traditional B-mode grayscale ultrasonography provides information on synovial thickness, and Doppler imaging measures the synovial blood flow. Ultrasound is easily accessible, rapid, and inexpensive. An important consideration is the reproducibility between readers. Whereas some studies found good or acceptable inter-reader agreement, other studies observed considerable variation between readers. US appears to be valuable, especially in the absence of abnormalities, and the negative predictive value of a normal US result is high. The prognostic implication of abnormal US findings is less clear.⁵ More long-term studies are needed to establish which US characteristics have a high positive predictive value for the development of persistent or erosive arthritis.

Until more data become available, the term *early synovitis* generally refers to synovitis that is detected by physical examination. It is important to note that early synovitis refers to a disease symptom but does not reflect any specific diagnosis. The spectrum of final diagnoses in a population of early synovitis patients is presented in [Figure 72-1](#).

EARLY ARTHRITIS CLINICS

Early arthritis clinics are population-based inception cohorts in which patients with synovitis of early onset are included and followed prospectively. These cohorts often contain a wealth of phenotypic information, and the longitudinal design allows the study of factors related to a beneficial or severe course of the disease. Such studies might increase our understanding of the processes involved in arthritis progression. A summary of existing early arthritis cohorts is presented in [Table 72-1](#). Inclusion criteria have changed over

Figure 72-1 Overview of diagnoses of early arthritis patients. (Presented data are based on 2284 early synovitis patients included in the Leiden Early Arthritis Clinic cohort and their diagnosis after 1 year of follow-up.) RS3PE, remitting seronegative symmetrical synovitis with pitting edema; SLE, systemic lupus erythematosus; UCTD, undifferentiated connective tissue disease.

time, in parallel with changing interpretations of the term *early*. Whereas the early arthritis clinics started in or before the 1990s allow inclusion of patients with symptoms up to 2 years, recently started early arthritis clinics focus on very early arthritis and include patients with symptoms less than 12 weeks.

WHAT IS UNDIFFERENTIATED ARTHRITIS?

The term *undifferentiated arthritis* (UA) refers to a subpopulation of early synovitis patients who do not meet criteria for other diseases, including infections, spondyloarthropathies, crystal diseases, and RA. Because it is a diagnosis of exclusion, no classification criteria for UA exist.

European early arthritis cohorts observed that 35% to 54% of the patients included do not meet criteria for other diseases and are considered as UA^{6,7}; in the remaining early synovitis patients, a definitive diagnosis could be established at first visits. The frequency of UA is dependent on symptom

duration at the time of the first visit to a rheumatologist. The longer symptoms exist, the more likely that sufficient characteristics are evident to support a definitive diagnosis, and the lower the prevalence of UA will be. In addition, the prevalence of UA will change when classification criteria for rheumatologic diseases change. For example, when the 1987 American College of Rheumatology (ACR) criteria for RA were applied to new-presenting early synovitis patients in the context of an early arthritis clinic in Europe (e.g., Leiden, the Netherlands), about 20% of those patients directly fulfilled the 1987 ACR criteria and thus were classified as RA. At present, few studies evaluating the performance of the 2010 ACR/European League Against Rheumatism (EULAR) criteria are yet available. Initial data from the Leiden clinic suggest that this percentage is increased when the 2010 criteria for RA are applied.⁸ The new criteria for RA not only may lead to a lower prevalence of UA, they also may lead to changed patient characteristics in the UA group in that those patients who resembled RA most closely may have departed from the UA population and now are potentially classified as RA.

Characteristics of Undifferentiated Arthritis

Characteristics at first presentation between patients who present with early UA and early RA using the 1987 criteria are somewhat different. Patients with recent-onset UA are younger (mean age, 48 vs. 57 years) and are less frequently female (58% vs. 66%) than early RA patients. UA patients generally have fewer swollen joints and have a greater likelihood of asymmetric synovitis. UA and RA patients do not differ in the acuteness of the start of their complaints, body mass index (BMI), or frequency of a positive family history for RA.⁹ UA patients have fewer bone erosions at baseline; in a recent study, erosions were present in 18% of UA patients and 35% of RA patients.¹⁰ Important differences were also noted with regard to autoantibodies. UA patients are RF positive in only 14% and anticitrullinated protein antibody (ACPA) positive in 12% of cases, whereas both of these values are 55% in patients with early RA.^{5,6} According to both the 1987 and the 2010 classification criteria for RA, the presence of ACPAs in patients with arthritis is not equal to the classification of RA. Particularly in the case of monoarthritis or oligoarthritis, patients may not fulfill criteria for RA and are labeled as UA. However, early UA patients with ACPAs have a chance of about 70% of classifying under the 1987 ACR criteria 1 year later.

REMISSION RATES IN UNDIFFERENTIATED ARTHRITIS AND RHEUMATOID ARTHRITIS

The natural disease course of UA is variable, depending on the inclusion criteria and the duration of symptoms in several inception cohorts. Spontaneous remission occurs in 40% to 55% of UA patients. In contrast, the remission rate in RA is at most 10% to 15%.^{12,13} In these studies, remission was defined as the absence of swollen joints for 1 year or longer after discontinuation of eventual disease-modifying antirheumatic drug (DMARD) therapy and/or discontinuation of participation in the outpatient clinic because the

Table 72-1 Overview of Early Arthritis Cohorts*

Cohort	Inclusion Criteria	Year of Onset	Includes Early Arthritis (Symptoms <2 yr)	Includes Very Early Arthritis (Symptoms <3 mo)
Wichita Arthritis Centre	Undifferentiated polyarthritis syndrome or RA Disease duration <2 yr	1973	X	
Norfolk Arthritis Register	Early inflammatory polyarthritis Age ≥16 yr ≥2 swollen joints Symptom duration ≥4 wk	1989	X	
Leiden EAC	Synovitis of ≥1 joint Symptom duration <2 yr Age >16 yr	1993	X	
Austrian Early Arthritis Registry	Inflammatory arthritis Symptom duration <12 wk	1995		X
Amsterdam	Synovitis of ≥2 joints Symptom duration <3 yr Age >18 yr	1995	X	
Leeds Early Arthritis Centre	Undifferentiated arthritis of the hands Symptom duration <12 mo	1995	X	
Birmingham VEAC	Synovitis of at least one joint Symptom duration ≤3 mo	2000		X
ESPOIR cohort study	Certain RA and UA that may develop into RA Symptom duration <6 mo Age 18-70 yr ≥2 inflammatory joints for the past 6 wk	2002	X	
Toronto Early Arthritis Cohort	Age >16 yr Symptom duration between 6 wk and 12 mo ≥2 swollen joints or 1 swollen MCP or PIP joint with one or more of the following: positive RF, positive ACPA, morning stiffness >45 min, response to NSAIDs, or painful metatarsophalangeal squeeze test	2003	X	
Berlin EAC	≥2 swollen joints Symptom duration between 4 wk and 12 mo	2004	X	
Norwegian Very Early Arthritis (NOR-VEAC)	Synovitis of at least one joint Symptom duration of 16 wk	2004		X
New Castle EAC	Synovitis of at least one joint or inflammatory complaints without a synovitis at physical examination	2006	X	
Rotterdam Early Arthritis CoHort (REACH)	Synovitis ≥1 joint or ≥2 tender joints Symptom duration ≤1 yr	2007	X	

*The presented cohorts include not only early RA patients but also a broader range of early synovitis patients.

ACPA, anticitrullinated protein antibody; MCP, metacarpophalangeal; NSAIDs, nonsteroidal anti-inflammatory drugs; PIP, proximal interphalangeal; RA, rheumatoid arthritis; UA, undifferentiated arthritis.

rheumatologist classified this patient as being in remission. Longer-term follow-up is needed to determine whether symptoms recur many years later. In addition to the difference in frequency of spontaneous remission in UA and RA, the disease duration when spontaneous remission is achieved differs as well. A recent study observed that within UA, the median disease duration until spontaneous remission is 17 months, whereas in RA patients, it takes a median period of 40 months before remission is achieved.⁹ Thus, the chance of achieving a natural remission is reduced as the disease process matures. This supports the notion that chronicity might be more easily reversed in the undifferentiated phase of disease.

JOINT DESTRUCTION IN UNDIFFERENTIATED ARTHRITIS AND RHEUMATOID ARTHRITIS

Validated scoring methods are available to measure joint destruction objectively. Most scoring methods assess a

limited number of joints. For example, the Sharp-van der Heijde method evaluates metacarpophalangeal (MCP), proximal interphalangeal (PIP), wrist, and metatarsophalangeal (MTP) joints but does not evaluate the distal interphalangeal or larger joints. Therefore, this method may be less optimal for measuring the level of joint damage in patients who present with predominant synovitis in large joints. In RA, the extent of joint destruction in small joints adequately reflects joint destruction in larger joints. Such data are missing for UA patients.

A recent study evaluated the subgroup of UA patients who developed RA later in time. Radiologic data were compared with those of patients who at first presentation of the disease directly fulfilled the 1987 ACR criteria for RA. Radiographic progression rates between these groups were not different. Health Assessment Questionnaire (HAQ) scores and Disease Activity Score (DAS) measures also were not different between these two groups.¹⁴ Thus, although UA patients as a group have a higher rate of spontaneous remission compared with patients with RA, the subgroup of UA patients who progress to RA have an

equally severe course compared with patients classified as RA earlier in the disease. Studies that compare the rate of joint destruction in the total group of early UA patients versus that of patients with early RA have not been performed.

BIOLOGIC MECHANISMS IN UA AND DETERMINANTS OF PROGRESSION TO RA

Our understanding of the processes responsible for progression from UA to RA is far from complete. Risk factors that were identified as independent predictors for RA development may provide clues:

- **Age:** The incidence of RA is clearly age dependent with a rising incidence from 7/100,000 for the age group 18 to 34 years to 107/100,000 for the age group 75 to 84 years.¹⁵ It is unknown why this is so; putative mechanisms include age-related decline in cellular, humoral, and innate immunity.
- **Gender:** Women who present with UA have a twofold greater chance of developing RA compared with men presenting with UA.¹⁵ Sex hormones influence predisposition to autoimmune disease. In general, men are less prone than women. Androgens have anti-inflammatory effects, and estrogens have been reported to suppress arthritis as well.^{16,17} Both estrogen and androgen inhibit bone resorption.¹⁸ These results may account for increased progression in postmenopausal females.
- **Number of involved joints and C-reactive protein:** Both markers reflect the level of inflammation and are frequently reported to be associated with progression of synovitis and worse disease outcomes. Although the number of swollen joints and the level of C-reactive protein (CRP) are correlated on a group level, this is often not the case in individual patients, and both markers have their own, independent predictive value. UA patients presenting with CRP levels greater than 50 mg/L have a five times increased risk of being in an early stage of RA. Likewise, patients classified with UA who have polyarthritis have a 1.5 times higher chance of fulfilling the criteria for RA later on compared with patients with monarthritis or oligoarthritis. Moreover, the risk that an early UA patient who has more than 10 swollen joints will develop RA is three times greater than that of patients with monarthritis or oligoarthritis.
- **Autoantibodies:** ACPAs as well as rheumatoid factor (RF) can be present years before the first clinical symptom of synovitis is noted; they are a risk factor for a persistent and destructive course of synovitis. Spontaneous remission is uncommon in ACPA-positive patients. Not only the presence but also the level of ACPAs is of predictive relevance. Despite these strong associations, studies that formally prove that ACPAs themselves are causally related to disease progression are lacking.
- **Environmental factors:** Early UA patients who smoke have a higher risk of development of RA and a

destructive disease course. This risk is confined to patients who carry HLA-DRB1 alleles that encode for the so-called shared epitope. Persons who smoke and also carry an HLA-DRB1 shared epitope allele are particularly prone to develop ACPAs, which subsequently are associated with disease persistency and erosiveness.

- **Genetic factors:** Apart from the HLA-DRB1 shared epitope alleles, genetic factors associated with progression from UA to RA are not clearly identified. Most genetic risk factors for RA provide risk for ACPA-positive RA when compared with healthy controls. It is not clear whether these factors are associated with progression from UA to RA as well, and if so, whether such an association is independent of the strong association between ACPAs and development of RA. Identification of new genetic factors has fueled the study of their relevance. In a population of UA patients, information on currently known genetic risk factors for RA does not improve prediction of risk for RA compared with a prediction rule based on common clinical risk factors alone.¹⁹
- **Additional biomarkers:** The role of biomarkers in the diagnosis of UA is limited. Within RA, it is known that serologic levels of pro-matrix metalloproteinase (MMP)3, receptor activator of nuclear factor κ B (NF κ B) ligand (RANKL), and osteoprotegerin (OPG) correlate with the rate of joint destruction over time.²⁰ Biomarkers that specifically reflect or predict disease progression in early UA patients thus far remain unknown.

WINDOW OF OPPORTUNITY

The concept of a window of opportunity suggests that there is a period early in the course of the disease when the disease process can be altered or can even be reversed with a complete return to normality. Treatment during this period might have a greater effect than treatment at a later stage in terms of halting disease progression and achieving remission.²¹⁻²³ Several different aspects have been studied, including whether very early UA (<12 weeks) may be an immunopathologically distinct phase compared with later disease.

Studies that focused on synovial tissue did not reveal differences.²⁴ It is difficult to come to a conclusion from negative studies because one never knows whether the relevant processes have been studied. However, studies that focused on the composition of autoantibody responses have demonstrated that profound maturation of the autoantibody response occurs early during disease.²⁵

UA patients who present to an early arthritis clinic within 12 weeks of symptom onset less often progress toward RA compared with UA patients with symptom duration greater than 12 weeks. Similarly, RA patients who at their first visit to a rheumatologist reported symptoms for less than 12 weeks had a lower rate of joint destruction over time and achieved sustained DMARD-free remission more often than RA patients who reported a period greater than 12 weeks before seeing a rheumatologist.²⁶

Support for the presence of a window of opportunity is also obtained from trials.²⁷ An unblinded study of a single dose of corticosteroids in patients with mild early inflammatory arthritis (median, 20 weeks) found that the strongest predictor of disease remission at 6 months (defined as the absence of symptoms and signs in patients without anti-inflammatory treatment) was disease duration less than 12 weeks at the time of therapy.²⁸ Clinical and radiologic outcomes were significantly better at 3 years in patients who started DMARD therapy within 3 months (“very early”) after disease onset compared with a median duration of 12 months at the start of treatment (“early”).²² Remission was achieved in 50% of the very early group compared with 15% of the early group. These data suggest that treatment in very early arthritis might have a greater effect on disease progression and thus underline the relevance of identification and treatment of arthritis in the very early disease phase.

TREATMENT OF UNDIFFERENTIATED ARTHRITIS

Although many rheumatologists have experience treating UA patients, formal data providing information on treatment of UA patients are lacking. Thus far, only a few trials have been performed in UA patients; these are summarized in Table 72-2. One trial observed an effect of steroids in early UA patients—an observation that was not reproduced in another study. Methotrexate is reportedly beneficial in UA patients and is associated with delayed progression to RA and a reduction in the rate of joint destruction. This effect appeared to be predominant among ACPA-positive UA patients but was negligible in ACPA-negative UA patients. However, when methotrexate was discontinued, the rate progression to RA was similar to the placebo arm.

Some biologics have been studied in UA patients. Although surprising lack of efficacy was observed with tumor necrosis factor (TNF) blockers, abatacept was beneficial. The heterogeneous nature of UA patients and the more favorable disease outcome and spontaneous remission rate make it difficult to observe treatment efficacy in the total UA group. Thus the placebo-treated group can have a good remission rate, and differences from the treatment group might be difficult to detect. None of the published

randomized trials in UA patients addressed this problem of heterogeneity and stratified patients having a high chance of developing RA or of having a spontaneous remission.

Individualized Treatment of Undifferentiated Arthritis

UA has a variable disease course, ranging between spontaneous remission and severe destruction. Because of this, and because DMARD therapy is potentially toxic, treatment of UA patients should be personalized. The chance for individual patients to progress toward RA or to have a persistent erosive disease course can be estimated using prediction models.^{29,30} One of the present prediction rules (Figure 72-2A) is validated using data from early arthritis clinics from Germany, the United Kingdom, Canada, Russia, and Japan; this algorithm is currently used in daily practice in several countries.^{29,31-36} The discriminative ability of this model is high. The prediction rule consists of nine variables: age, gender, distribution of involved joints, morning stiffness, numbers of tender and swollen joints, CRP level, and presence of RF and ACPAs. It calculates the risk of developing RA for every UA patient (Figure 72-2B). Such information can facilitate the decision of whether or not to initiate DMARD therapy and might facilitate patient involvement in decision making. In general, a score of 6 or lower is related to a low chance of developing RA (91% chance of not developing RA) and may be a reason to not initiate DMARD therapy. In contrast, patients with a score of 8 or higher have an 84% chance of developing RA; this might be a reason to initiate DMARD therapy in some patients.

Can the 2010 ACR/EULAR criteria³⁷ be used to identify UA patients who actually have early RA? The presence of new criteria for RA is relevant in that the absence of up-to-date classification criteria had hampered progress with regard to treatment strategies in early RA. The 1987 ACR criteria for RA were not designed to classify RA early and did not include more recent autoantibody tests or imaging modalities. Most randomized clinical trials included patients who fulfilled the 1987 criteria, hence patients with established RA. It is not clear whether the efficacy observed in these trials is the same for patients with early RA or UA.

Table 72-2 Randomized Controlled Trials in Patients with Early Undifferentiated Arthritis

Trial	N	Treatment	Follow-up Duration	Outcome	Effect Compared with Placebo
SAVE trial ³⁸	389	Single IM injection 120 mg methylprednisolone	52 wk	Drug-free clinical remission	No effect
STIVEA trial ³⁹	265	3 IM injections 80 mg methylprednisolone	6 and 12 mo	Need to start DMARDs	At 6 mo 61% vs. 76% had started DMARDs; At 12 mo 10% vs. 20% had resolved disease
PROMPT trial ⁴⁰	110	Methotrexate therapy during 12 mo	30 mo	Fulfilling the 1987 ACR criteria	40% vs. 53% developed RA; lower radiologic progression
ADJUST trial ⁴¹	56	Abatacept treatment during 6 mo	12 mo	Fulfilling the 1987 ACR criteria	46% vs. 67% developed RA; no effect on radiographic progression
Saleem et al ⁴²	17	Infliximab at 0, 2, 4, and 16 wk	26 wk	Clinical remission	No effect observed

ACR, American College of Rheumatology; DMARDs, disease-modifying antirheumatic drugs; IM, intramuscular; RA, rheumatoid arthritis.

FORM TO CALCULATE A PATIENT'S PREDICTION SCORE

1. What is the age?	Multiply with 0.02		_____
2. What is the gender?	In case female:	1 point	_____
3. How is the distribution of involved joints?			
	In case small joints hands and feet:	0.5 point	_____
	In case symmetric	0.5 point	_____
	In case upper extremities	1 point	_____
	Or: In case upper and lower extremities	1.5 points	_____
4. What is the length of the VAS morning stiffness (range 0-100 mm)?			
	In case 26-90 mm	1 point	_____
	In case >90 mm	2 points	_____
5. What is the number of tender joints?			
	In case 4-10	0.5 points	_____
	In case 11 or higher	1 point	_____
6. What is the number of swollen joints?			
	In case 4-10	0.5 point	_____
	In case 11 or more	1 point	_____
7. What is the C-reactive protein level (mg/L)?			
	In case 5-50	0.5 point	_____
	In case 51 or higher	1.5 points	_____
8. Is the rheumatoid factor positive?	If yes	1 point	_____
9. Are the anticitrullinated protein antibodies positive?	If yes	2 points	_____
		Total score	_____

SUBJECTS' PREDICTION SCORES PLOTTED VERSUS THE PREDICTED RISK TO DEVELOP RA

B

Figure 72-2 Tool to predict an individual early arthritis patient's probability of developing rheumatoid arthritis (RA). With the calculated prediction score (A), the probability can be derived (B).²⁹ VAS, visual analog scale.

The new criteria have mainly been derived for classification and research purposes³⁷ and require validation for use in clinical practice for early synovitis. The 2010 criteria should not be used as diagnostic criteria until it is demonstrated that patients who fulfill them have a high chance for a persistent or destructive disease course, making 2010 criteria positivity the basis of an argument for starting disease-modifying drugs.

Sjögren's Syndrome

E. WILLIAM ST. CLAIR

KEY POINTS

Sjögren's syndrome is divided into primary and secondary forms. The primary form occurs in approximately 0.1% to 0.6% of the general population.

The clinical hallmarks of Sjögren's syndrome are keratoconjunctivitis sicca (dry eyes), xerostomia (dry mouth), and parotid gland swelling.

Extraglandular features of primary Sjögren's syndrome include fatigue, Raynaud's phenomenon, polyarthralgia/arthritis, interstitial lung disease, neuropathy, and purpura.

A chronic mononuclear cell infiltration of the lacrimal and salivary glands is the characteristic histopathologic finding.

A diagnosis of primary Sjögren's syndrome is made by subjective and objective assessment of dry eyes and dry mouth, testing for serum antinuclear antibodies including anti-Ro/SS-A and anti-La/SS-B antibodies, and labial salivary gland biopsy.

Treatment of Sjögren's syndrome aims to provide symptomatic improvement in the symptoms of dry eyes and dry mouth, as well as control of extraglandular manifestations of disease.

HISTORICAL PERSPECTIVE

In 1888 Johann von Mikulicz-Radecki described a case of bilateral painless swelling of the lacrimal, parotid, and submandibular glands,¹ an entity that later bore his name. Reports soon followed showing Mikulicz disease was not a distinct pathologic entity but rather a clinical potpourri of conditions including leukemia, lymphoma, and tuberculosis. Shortly thereafter, salivary gland disease became linked with dryness of the eyes and oral mucosa when Henri Gougerot, a well-known and successful French dermatologist, wrote in 1925 about three cases of salivary gland atrophy with dryness of the eyes, mouth, and vagina. The modern concept of Sjögren's syndrome was firmly rooted in 1933 when Henrik Sjögren, a Swedish ophthalmologist, reported a series of 19 cases of keratoconjunctivitis sicca including two cases with swelling of the major salivary glands.² Over the next 2 decades, Sjögren and others published extensively about various facets of the disease that now carries his name (also called Gougerot-Sjögren disease), with most of these contributions coming from European ophthalmologists.

In 1953 Morgan and Castleman³ published their detailed histopathologic findings from 18 patients with enlarged lacrimal and salivary glands. This pathologic treatise consisted of cases without apparent etiology that had clinical features

resembling those of Mikulicz's disease and Sjögren's syndrome. Notably, 15 of the 18 patients were women with lacrimal and salivary gland swelling that developed in the fifth and sixth decades of life. Morgan and Castleman found in the salivary gland tissue a consistent "lymphoid element" accompanied by a striking proliferation of myoepithelial and epithelial cells. The epithelial changes produced a characteristic narrowing or obliteration of the ductal lumen, forming cords of solid cell masses they called *epimyoeplithelial islands*. Because of the prominence of these epithelial structures, they advanced the theory that Mikulicz disease had its origins in the ductal epithelium. Morgan and Castleman also recognized that the salivary gland pathology in their cases was similar to that of the patients described by Henrik Sjögren with keratoconjunctivitis sicca. Because Sjögren's patients were mostly middle-aged women, Morgan and Castleman reasoned that Mikulicz disease was a subset of Sjögren's disease but with incomplete clinical manifestations. This now classic paper had the effect of unifying Mikulicz disease and Sjögren's syndrome into a single disease entity, a belief that dominated the field until recently.

When Joseph J. Bunim delivered the Heberden Oration at the Wellcome Foundation in London on December 2, 1960, he enlightened his audience about the latest advances in Sjögren's syndrome.⁴ Bunim described in detail the clinical, pathologic, and laboratory findings of the 40 patients with Sjögren's syndrome evaluated by himself, Kurt Bloch, Martin Wohl, Richard Oglesby, and Irwin Ship at the Clinical Center of the National Institutes of Health (NIH). All patients in their series had at least two of the three following features: keratoconjunctivitis sicca, xerostomia (with or without enlargement of the salivary glands), and rheumatoid arthritis. Bunim also knew from the work of others that keratoconjunctivitis sicca and xerostomia, or sicca complex, occurred in some patients with systemic lupus erythematosus, scleroderma, polymyositis, and polyarteritis nodosa. He brought home the point that the exocrinopathy extended beyond the lacrimal and salivary glands to affect the pharynx, larynx, and trachea, as well as the vagina. Many of their patients with Sjögren's syndrome also had extraglandular manifestations such as Raynaud's phenomenon, purpura, pulmonary infiltrates on chest radiograph, and peripheral neuropathy. Talal and Bunim took note of the diagnosis of reticulum cell sarcoma (an older term that includes non-Hodgkin's lymphoma) in three patients and Waldenström's macroglobulinemia in a fourth patient from the NIH cases, drawing attention for the first time to the increased risk of developing lymphoma in this disease.⁵ In this report, they speculate that a "chronic state of immunologic hyperactivity and the proliferation of immunologically competent cells producing abnormal tissue antibodies

predisposes to the relatively frequent development of malignant lymphoma.”⁵

The NIH group also pioneered the characterization of the serologic markers of Sjögren’s syndrome. In 1965 they reported that 12 of their 16 patients (75%) with sicca symptoms but no evidence of another connective tissue disease had serum antinuclear antibody (ANA) reactivity by indirect immunofluorescence on rat liver tissue.⁶ Applying the Ouchterlony plate method, they further showed that sera from 13 of 16 (81%) of these patients contained precipitating antibodies to SjD and SjT, which were later to be called anti-Ro (SS-A) and anti-La (SS-B) antibodies. Moreover, Bloch and colleagues⁷ set the stage for our modern classification schemes by subdividing their patients at the NIH into primary and secondary Sjögren’s syndrome. Secondary Sjögren’s syndrome was the category reserved for patients with sicca symptoms in the setting of another connective tissue disease such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, or dermatomyositis, whereas primary Sjögren’s syndrome was the designation when the sicca complex occurred in the absence of another connective tissue disease.

In the late 1960s and early 1970s, the investigation of labial salivary gland biopsy for the diagnosis of Sjögren’s syndrome led to the development of grading systems for quantifying the intensity of tissue inflammation. In 1968 Chisholm and Mason proposed a grading system for labial salivary gland biopsies that used a simple grading scale (0 to 4) in which grades 0, 1, and 2 represented absent, slight, and moderate mononuclear cell infiltrates, respectively.⁸ The higher grades of 3 and 4 corresponded to focal inflammatory cell scores of 1 and greater than 1 per 4 mm² of tissue, where a focus equated to an aggregate of 50 or more mononuclear cells. In this initial study, 9 of the 10 patients with Sjögren’s syndrome were classified as grade 3 ($n = 3$) or grade 4 ($n = 6$). By comparison, biopsies had lower grades when they were taken from patients with other chronic inflammatory conditions, as well as controls. For example, among 10 patients with rheumatoid arthritis, the highest biopsy grade was only 3. Twenty other subjects with a variety of other rheumatic diseases (e.g., osteoarthritis, reactive arthritis, psoriatic arthritis, scleroderma) had biopsies with grades of 0 or 1. Although it was a small study by today’s standards, this work inspired others to validate and refine these findings. Later, postmortem biopsies from 116 controls without a history of an inflammatory disease were scored with only grade 0, 1, or 2 infiltrates, attesting to the diagnostic specificity of this grading system.⁹ However, the Chisholm and Mason grading system had limitations because it was sensitive only at the lower end of the scale and did not discriminate among biopsies with the highest degree of cellular infiltrates or biopsies with two or more foci per 4 mm² of tissue.

To improve on these earlier efforts, Tarpley and co-workers¹⁰ at the NIH developed a grading system that incorporated scales for not only estimating the extent of inflammation but also quantifying the amount of acinar destruction. As expected, they found that labial salivary gland biopsies from patients with the sicca complex alone had higher grades of cellular infiltrates and acinar destruction than those with sicca symptoms and rheumatoid arthritis or rheumatoid arthritis alone. However, grading the

acinar destruction did not add diagnostic value independent of the severity of the infiltrates. Greenspan and colleagues¹¹ from the University of California at San Francisco modified the Chisholm and Mason grading scale when they examined labial salivary gland biopsies from 54 patients with definite or probable Sjögren’s syndrome together with 21 controls. Their results reinforced the diagnostic relevance of the focus score, including its relationship to focus size, and highlighted the presence of germinal centers.¹¹ Grade 4 biopsies (>1 focus per 4 mm² of tissue) were primarily found in the patients with Sjögren’s syndrome, with the highest focus scores in patients with the sicca complex in the absence of another connective tissue disease. The range for the focus score was extended from 1 to 12, where a score of 12 was arbitrarily assigned to those specimens with foci so numerous that they were confluent. The focus score was thereafter adopted as the “gold standard” for quantifying chronic inflammation in labial salivary gland biopsies. Because the signs and symptoms of xerostomia were relatively nonspecific indicators of salivary gland involvement in Sjögren’s syndrome, other methods such as sialometry, chemical analysis of the saliva, sialography, and scintigraphy were also explored for diagnosing this condition. However, these measures of salivary flow and duct anatomy proved to be diagnostically nonspecific; sialography and scintigraphy had other shortcomings limiting their clinical use.

With a growing interest in Sjögren’s syndrome, investigators began to develop classification criteria for comparison of results across studies. In the 1980s, many groups proposed classification criteria for Sjögren’s syndrome, aiming to identify patients with a sicca complex caused by a chronic autoimmune disorder. These proposed criteria incorporated a combination of the following items: symptoms of the ocular and oral components; objective measures of lacrimal and salivary gland involvement; a focus score greater than or equal to 1 from a labial salivary gland biopsy; and the presence of serum autoantibodies. Many investigators from Europe, the United States, and Japan contributed to this effort, leading to the general acceptance in 2002 of the revised version of the European criteria proposed by the American-European Consensus group.¹² The International Sjögren’s Syndrome Registry, funded in 2003, is collecting data that will inform the natural history of Sjögren’s syndrome. It will also support validation of new criteria sets that may be developed from the baseline data of the more than 1200 patients across the world with suspected primary or secondary Sjögren’s syndrome.

DEFINITIONS AND CLASSIFICATION CRITERIA

The clinical hallmarks of Sjögren’s syndrome are keratoconjunctivitis sicca and xerostomia, or the sicca complex. The term “keratoconjunctivitis sicca” is derived from Latin, and its translation is “dryness of the cornea and conjunctiva.” Xerostomia refers to the subjective symptoms of dry mouth. Sjögren’s syndrome is subdivided into primary and secondary Sjögren’s syndrome. The category of secondary Sjögren’s syndrome is reserved for patients with keratoconjunctivitis sicca or xerostomia, or both, in the setting of another connective tissue disease or chronic inflammatory process such

as rheumatoid arthritis, systemic lupus erythematosus, polymyositis, systemic sclerosis (scleroderma), or granulomatosis with polyangiitis (formerly Wegener's granulomatosis). Patients are diagnosed with primary Sjögren's syndrome if they manifest signs and symptoms of keratoconjunctivitis sicca and xerostomia in the absence of another connective tissue disease provided they meet serologic or histopathologic criteria. Because primary Sjögren's syndrome is associated with extraglandular features that overlap with those of other connective tissue diseases, it may be difficult in some cases to distinguish from patients with secondary Sjögren's syndrome. The challenge in distinguishing between primary and secondary forms of the disease arises most often in patients with primary Sjögren's syndrome and overlapping features of lupus such as rash, arthritis, and leukopenia. This distinction is often a matter of semantics depending on the preference for "lumping" as opposed to "splitting."

Other terms used to describe Sjögren's syndrome are *autoimmune exocrinopathy*¹³ and *autoimmune epithelitis*.¹⁴ In Sjögren's syndrome, the term *exocrinopathy* receives emphasis because of the generalized glandular involvement causing dysfunction of the lacrimal and salivary glands, as well as the apocrine sweat glands of the skin and the submucosal glands of the nose, pharynx, larynx, large airways, and vagina. The term *epithelitis* gains footing from the uniformly activated epithelial cells omnipresent in the lacrimal and salivary glands and other sites of glandular involvement.

International agreement has been reached on the classification of Sjögren's syndrome. By the early 1980s, several criteria sets had been proposed for the classification of Sjögren's syndrome including the Copenhagen criteria,¹⁵ the Japanese criteria,¹⁶ the Greek criteria,¹⁷ and the California criteria.¹⁸ Common to each of these criteria sets was the requirement for objective evidence of keratoconjunctivitis sicca and salivary gland involvement. They differed, however, in their item content and weighting, as well as the methods for assessing salivary gland involvement. For example, some of the criteria relied on whole salivary flow (Copenhagen), whereas other criteria relied on parotid flow rate (Greek, California). Only two of the criteria sets discriminated between primary and secondary Sjögren's syndrome (Copenhagen and Greek).

Movement toward consensus began when the Epidemiology Committee of the European Community conducted a multicenter study involving 26 centers from 12 countries aimed at developing criteria for the classification of Sjögren's syndrome. This group first agreed on the items that should be included in the classification criteria for Sjögren's syndrome and then tested their operational characteristics in a large sample of patients with a clinical diagnosis of primary Sjögren's syndrome ($n = 246$), secondary Sjögren's syndrome ($n = 201$), other connective tissue diseases without Sjögren's syndrome ($n = 113$), and healthy controls ($n = 133$).¹⁹ Two sets of three questions were selected from a larger body of questions that best correlated with the presence of keratoconjunctivitis sicca and xerostomia, respectively, as judged by clinical experts. The results from objective tests were analyzed by univariate analyses, yielding a tentative list of items based on their sensitivity and specificity for correct classification of the diagnosis. The following six items were chosen for the classification criteria: (I) ocular symptoms; (II) oral symptoms; (III) ocular signs (Schirmer-I-test

≤ 5 mm/5 min or Rose Bengal score ≥ 4 by the van Bijsterveld scoring system); (IV) histopathologic features (focus score ≥ 1 on labial salivary gland biopsy); (V) objective evidence of salivary gland involvement by at least one abnormal test (salivary scintigraphy, parotid sialography, or unstimulated salivary flow rate ≤ 1.5 mL/15 min); and (VI) at least one of the following serum autoantibodies: anti-Ro/SS-A or anti-La/SS-B antibodies, ANAs, or rheumatoid factor. Exclusion criteria were pre-existing lymphoma, acquired immunodeficiency syndrome, sarcoidosis, and graft-versus-host disease. The presence of four of six criteria (accepting only a positive test for anti-Ro/SS-A or anti-La/SS-B antibodies for item VI had good sensitivity (93.5%) and specificity (94%) for correctly classifying a patient with primary Sjögren's syndrome. It was suggested to be the optimal combination for efficient classification of this condition. For classification of secondary Sjögren's syndrome, the best combination was found to be a positive response for items I or II plus a positive result for any two of items II, IV, and V, resulting in a sensitivity of 85.1% and specificity of 93.9% for this diagnosis. With a positive response to items I or II and only one positive response to items III to V, the sensitivity increased to 95.6% but the specificity dropped to 71.6%.

These preliminary European classification criteria for Sjögren's syndrome were validated in a second study of similar design. Cases of primary Sjögren's syndrome ($n = 81$), secondary Sjögren's syndrome ($n = 76$), other connective tissue diseases without Sjögren's syndrome ($n = 54$), and controls ($n = 67$) were assembled by expert clinicians at 16 centers from 10 countries to validate the initial results.²⁰ In this study, it was decided not to use items III (a) (Schirmer-I-test) and V (c) (unstimulated whole salivary flow) to classify patients older than age 60 because the tear and salivary flow by these measures were significantly reduced in the elderly controls from the original study. The results proved to be similar to those of the earlier study, showing a sensitivity of 97.5% and specificity of 94.2% for correctly classifying primary Sjögren's syndrome and a sensitivity of 97.3% and specificity of 91.8% for correctly classifying secondary Sjögren's syndrome. A limitation of this type of study design is the possibility that the sensitivity and specificity of these criteria may be artificially inflated by a "circular bias" deriving from the results of the diagnostic testing on the original selection of patients. These preliminary European classification criteria have also been criticized because a patient may be classified with primary Sjögren's syndrome despite a negative biopsy and the absence of serum anti-Ro/SS-A or anti-La/SS-B antibodies. Thus patients may be classified as having primary Sjögren's syndrome without evidence of an immune basis for their condition.

This conceptual impasse was overcome by the European Study Group on Classification Criteria for Sjögren's Syndrome with a group of American experts. From their previous study, they selected a cohort of 76 patients with primary Sjögren's syndrome, 41 patients with another connective tissue disease but without Sjögren's syndrome, and 63 controls and tested three different combinations of items from the original classification criteria using a receiving operator curve (ROC) analysis. To determine the best possible prediction model, the optimal classifiers were compared with ROC analysis for the three different combinations: C point

(positivity for any four of the six items); C* point (positivity of any four of the six items, excluding cases negative for both items IV and VI); and D point (positive for any of the four objective criteria).¹² The C point and the C* point showed the same accuracy (92.7%); however, the C* point had a lower sensitivity than the C point (89.5% vs. 97.4%), but a higher specificity (95.2% vs. 89.4%), and was preferred on the basis of the goal of selecting criteria with a high probability of excluding patients without the disease. The sensitivity and specificity of the D point were 84.2% and 95.2%, respectively, and judged to be comparable with the C* point and acceptable for classification purposes. Therefore patients may now be classified as having primary Sjögren's syndrome if they fulfill four of the six items including either a positive labial salivary gland biopsy or a positive test for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies. This combination avoids the problem of classifying a patient with primary Sjögren's syndrome in the absence of a positive labial salivary gland biopsy or a positive

test for anti-Ro/SS-A and/or anti-La/SS-B antibodies. Alternatively, they may meet the criteria by satisfying any four of the objective items, which was a highly unusual scenario in their data set because nearly all patients with primary Sjögren's syndrome manifested symptoms of dry eyes and/or dry mouth.

The revised classification criteria proposed by the American-European Consensus Group are shown in Table 73-1. It was further specified that the Schirmer-I test be performed with anesthesia and that other ocular dyes such as lissamine green (for conjunctival staining) and fluorescein (for corneal staining) be allowed as replacements for Rose Bengal dye, which was not available in many countries. A positive labial salivary gland biopsy was further defined according to the rules set forth by Daniels and Whitcher.²¹ In this case, a positive biopsy must show evidence of focal lymphocytic sialadenitis (FLS), which they defined as dense aggregates of 50 or more lymphocytes in perivascular or periductal locations. These aggregates, or

Table 73-1 Revised International Classification Criteria for Sjögren's Syndrome (SS)

<p>I. Ocular symptoms: a positive response to at least one of the following questions:</p> <ol style="list-style-type: none"> 1. Have you had daily, persistent, troublesome dry eyes for more than 3 months? 2. Do you have a recurrent sensation of sand or gravel in the eyes? 3. Do you use tear substitutes more than 3 times a day? <p>II. Oral symptoms: a positive response to at least one of the following questions:</p> <ol style="list-style-type: none"> 1. Have you had a daily feeling of dry mouth for more than 3 months? 2. Have you had recurrently or persistently swollen salivary glands as an adult? 3. Do you frequently drink liquids to aid in swallowing dry food? <p>III. Ocular signs—that is, objective evidence of ocular involvement defined as a positive result for at least one of the following two tests:</p> <ol style="list-style-type: none"> 1. Schirmer's I test, performed without anaesthesia (≤ 5 mm in 5 minutes) 2. Rose bengal score or other ocular dye score (≥ 4 according to van Bijsterveld's scoring system) <p>IV. Histopathology: in minor salivary glands (obtained through normal-appearing mucosa), focal lymphocytic sialadenitis, evaluated by an expert histopathologist, with a focus score greater than 1, defined as a number of lymphocytic foci (which are adjacent to normal-appearing mucous acini and contain more than 50 lymphocytes) per 4 mm² of glandular tissue</p> <p>V. Salivary gland involvement: objective evidence of salivary gland involvement defined by a positive result for at least one of the following diagnostic tests:</p> <ol style="list-style-type: none"> 1. Unstimulated whole salivary flow (≤ 1.5 mL in 15 minutes) 2. Salivary scintigraphy showing delayed uptake, reduced concentration, and/or delayed excretion of tracer <p>VI. Autoantibodies: presence in the serum of the following autoantibodies:</p> <ol style="list-style-type: none"> 1. Antibodies to Ro(SSA) or La(SSB) antigens, or both 	
Revised Rules for Classification	
For Primary SS	
In patients without any potentially associated disease, primary SS may be defined as follows:	
<ol style="list-style-type: none"> a. The presence of any 4 of the 6 items is indicative of primary SS, as long as either item IV (Histopathology) or VI (Serology) is positive. b. Any 3 of the 4 objective criteria items (i.e., items III, IV, V, and VI) are present. c. The classification tree procedure represents a valid alternative method for classification, although it should be more properly used in clinical-epidemiologic surveys. 	
For Secondary SS	
In patients with a potentially associated disease (for instance, another well-defined connective tissue disease), the presence of item I or item II plus any 2 from among items III, IV, and V may be considered as indicative of secondary SS.	
Exclusion Criteria	
<p>Past head and neck radiation treatment</p> <p>Hepatitis C infection</p> <p>Acquired immunodeficiency syndrome</p> <p>Pre-existing lymphoma</p> <p>Sarcoidosis</p> <p>Graft-versus-host disease</p> <p>Use of anticholinergic drugs (since a time shorter than fourfold the half-life of the drug)</p>	

Reproduced from Classification criteria for Sjögren's syndrome: a revised version of the European criteria proposed by the American-European Consensus Group, Vitali C, Bombardieri S, Jonsson R, et al and the European Study Group on Classification Criteria for Sjögren's Syndrome, *Ann Rheum Dis* 61:554–558, 2002 with permission from BMJ Publishing Group Ltd.

foci, must contain only a small proportion of plasma cells and be located adjacent to normal-appearing acini in lobules without duct dilatation or fibrosis. A minimum threshold for positivity was considered to be greater than or equal to 1 focus per 4 mm² of tissue. These rules are important to follow in the interpretation of labial salivary gland biopsies because many specimens, especially from elderly individuals, show patterns of inflammation consistent with chronic sialadenitis, namely mixed lymphocytic and plasma cell infiltrates in association with ductal dilation, acinar atrophy, and fibrosis.

An abnormal parotid sialogram has been clarified in the revised criteria as the presence of diffuse sialectasis according to the scoring system of Rubin and Holt.²² Positivity by salivary scintigraphy was also further defined as delayed uptake, reduced concentration, or delayed secretion of the tracer, using the method of Schall and colleagues.²³ Parotid sialography and salivary scintigraphy are rarely used clinically in the United States. The revised version also included some modifications to the list of exclusion criteria.

These new revised criteria have also not escaped criticism by some experts because of the possibility that patients may be classified as having primary Sjögren's syndrome without subjective or objective evidence of ocular involvement (satisfying items IV, V, and VI).²⁴ Others have mentioned the "histologic and immunologic bias" of the revised criteria,²⁵ but this argument fails if the goal of the classification criteria is to define patients with an immune-mediated condition. Some patients with primary Sjögren's syndrome will test positive for serum ANAs in the absence of anti-Ro/SS-A and anti-La/SS-B antibodies. If such patients have a falsely negative labial salivary gland biopsy, then they will not be classified as having primary Sjögren's syndrome despite a better than average chance otherwise. Another potential shortcoming is the lack of laboratory standardization for the detection of anti-Ro/SS-A and anti-La/SS-B antibodies. Many different methodologies are now available to measure these autoantibodies including the older Ouchterlony plate assay, various commercial enzyme-linked immunosorbent assay (ELISA) kits, and the newer multiplex bead technology. It is unclear if the type of methodology influences the sensitivity or specificity of these criteria. Although these classification criteria have been generally accepted by the medical community, they have not been officially endorsed by the American College of Rheumatology or the European League Against Rheumatism.

Recently, new classification criteria have been published based on data from the International Collaborative Clinical Alliance Cohort.^{25a} These criteria have been approved by the American College of Rheumatology. These criteria are derived solely from objective test results and require for classification of primary Sjögren's syndrome at least 2 of the following: (1) a positive test for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies *or* a positive test for rheumatoid factor and an ANA titer of $\geq 1:320$; (2) labial salivary gland biopsy exhibiting focal lymphocytic sialadenitis with a focus score ≥ 44 mm²; and (3) keratoconjunctivitis sicca with ocular staining score ≥ 3 . Using an external set of 303 participants, these classification criteria had a sensitivity of 92.5% and a specificity of 95.4%. Further validation of these criteria will be necessary to confirm their performance.

EPIDEMIOLOGY

Primary Sjögren's syndrome ranks among the most common of the autoimmune diseases, with a prevalence rate ranging from 0.1% to 4.6%.²⁶ However, the epidemiologic data are confounded by variations in the ages of the study populations and differences in the classification criteria used for case identification. For example, the application of the Copenhagen criteria yields a prevalence rate for Sjögren's syndrome 2.7-fold greater than the California criteria, whereas the preliminary European classification criteria captures 2- to 3-fold more patients than the Copenhagen criteria.²⁷ Bowman and colleagues²⁸ estimated the prevalence of primary Sjögren's syndrome at 0.1% to 0.6% in a community from the United Kingdom using the revised criteria proposed by the American-European Consensus Group. In a study from Greece employing these same criteria, the age-adjusted mean annual incidence and prevalence rates were 5.3 (confidence interval [CI], 4.5 to 6.1) per 10⁵ persons (0.5 for men and 10.1 for women) and 92.8 per 100,000 persons (8.4 for men and 177.4 for women), respectively.²⁹ The incidence and prevalence rates of primary Sjögren's syndrome are significantly higher in women than men (e.g., approximately 20:1), with a peak incidence in the fifth and sixth decades of life.²⁹ Primary Sjögren's syndrome occurs infrequently in children with onset as early as 5 years of age.³⁰ The revised criteria of the American-European Consensus Group may be less sensitive for classifying primary Sjögren's syndrome in children than adults owing to differences between these two age groups in the clinical presentation of this disease.³⁰

The prevalence of secondary Sjögren's syndrome associated with rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis has been estimated to be 17.1%,³¹ 8% to 20%,³²⁻³⁴ and 14%³⁵; respectively. To be classified as secondary Sjögren's syndrome, patients in these studies had at minimum symptoms of keratoconjunctivitis sicca or xerostomia and objective evidence of lacrimal or salivary gland involvement. None of these studies used the preliminary European classification criteria for secondary Sjögren's syndrome.

GENETICS AND PATHOGENESIS

Central to the pathogenesis of primary Sjögren's syndrome is the dysregulation of T cells and B cells, with key contributions from innate pathways of inflammation. Many of these same concepts may apply to the pathogenesis of secondary Sjögren's syndrome; however, most investigation into disease mechanisms has focused on patients with the primary form of the disease, and many of the immunologic features of secondary Sjögren's syndrome are driven by the pathogenic mechanisms underlying the associated disorders.

In primary Sjögren's syndrome, a common theme among models of disease pathogenesis is loss of immunologic tolerance to self-antigens. This failure to recognize self manifests in primary Sjögren's syndrome as the production of serum autoantibodies indicative of the loss of B cell tolerance. Because the appearance of serum autoantibodies may precede the onset of clinical disease, the loss of immune tolerance appears to be permissive but not sufficient to induce clinical disease. T cells reactive with several

candidate self-antigens have also been found infiltrating the labial salivary glands of patients with primary Sjögren's syndrome. However, the timing of the evolution of these aberrant T cell responses is unclear with respect to disease onset. Environmental or stochastic factors or both are likely to play in triggering the chronic inflammatory response in the context of a genetically predisposed innate and adaptive immune system.

Because a disproportionately high number of the cases of primary Sjögren's syndrome occur in women, the search for environmental candidates has centered on abnormal regulation of estrogens and androgens. However, no major differences have been found between patients with primary Sjögren's syndrome and healthy controls in serum levels of sex steroid hormones.³⁶ In addition, treatment with the hormone dehydroepiandrosterone, which acts on the androgen receptor, has shown no clinical efficacy in women with primary Sjögren's syndrome.³⁷ Among possible viral triggers, Epstein-Barr virus (EBV) and cytomegalovirus (CMV) have received attention in primary Sjögren's syndrome due to their suppressive effects on T cell immunity and their ability to establish persistent infection. In one study, EBV deoxyribonucleic acid (DNA) was found by immunohistochemical staining in salivary gland biopsies to localize in acinar and ductal epithelial cells³⁸; however, the available evidence does not otherwise support a direct role for EBV infection in the pathogenesis of this disease. A 94-bp fragment of cocksackievirus ribonucleic acid (RNA) was also shown to be differentially expressed in salivary gland biopsies from patients with primary Sjögren's syndrome compared with controls,³⁹ but these results were not replicated in a later study.⁴⁰ As yet, the identity of a possible viral trigger remains elusive, if indeed one exists.

It has been difficult to estimate the genetic risk for developing primary Sjögren's syndrome owing to the absence of large twin studies. However, the existence of many large families with two or more members with primary Sjögren's syndrome argues strongly for a genetic component to disease pathogenesis.⁴¹ Primary Sjögren's syndrome is considered to be a complex genetic disorder, similar to the genetic susceptibility of systemic lupus erythematosus and rheumatoid arthritis. It is now clear from genetic studies of human autoimmune diseases that multiple genes contribute to disease risk and that individually each gene confers only modest effects on disease susceptibility.⁴² The exception to this rule is the relatively strong signal associated with the human leukocyte antigen (HLA) locus on human chromosome 6p21.3. In populations of European descent, confirmed HLA associations with primary Sjögren's syndrome include DRB1*0301 (DR3), DRB1*1501 (DR2), DQA1*0103, DQA1*0501, DQB1*0201, and DQB1*0601.^{43,44} The disease-associated polymorphisms located in the DRB1*0301 and DRB1*1501 loci account for 90% of the HLA genetic contribution. The HLA locus appears to play a major role in the pathogenesis of autoantibody responses associated with primary Sjögren's syndrome. In patients with primary Sjögren's syndrome, higher titers of anti-Ro/SS-A and anti-La/SS-B antibodies have been linked to heterozygosity for the DQA1 and DQB1 alleles.⁴⁵

The genetic susceptibility to primary Sjögren's syndrome will likely include inheritance of genes identified as risk factors in other autoimmune diseases. Familial clustering of

cases of primary Sjögren's syndrome with systemic lupus erythematosus, rheumatoid arthritis, and systemic sclerosis, as well as other autoimmune diseases, are consistent with this premise.⁴⁶⁻⁴⁸ There have been no large-scale genome-wide association studies in primary Sjögren's syndrome. Most efforts to identify disease susceptibility genes in primary Sjögren's syndrome have taken the candidate gene approach. Genes in the type I interferon (IFN) pathway have been the focus of several candidate gene studies because they are highly expressed in the peripheral blood and salivary glands of patients with primary Sjögren's syndrome compared with controls.⁴⁹ In a small cohort study, an increased risk of primary Sjögren's syndrome was associated with a single nucleotide polymorphism in the splicing sequence of exon B of the gene encoding IFN regulatory factor 5 (IRF5).⁵⁰ IRF5 is among the nine IRFs that signal through Toll-like receptors (TLRs) and is essential for inducing responses through TLR4, 7, and 9.⁵¹ Given the possible inciting roles of viral RNA and DNA, the endosomal TLR7 and TLR9 pathways may be important in primary Sjögren's syndrome for the activation of the type I IFN pathway.⁵² A 5-bp insertion/deletion polymorphism (CGGGG insertion/deletion) in the promoter region of the IRF5 transcript has also been linked to primary Sjögren's syndrome.⁵³ This polymorphism appears to have functional significance because reovirus (double-stranded RNA virus)—infected salivary gland epithelial cells in culture bearing this polymorphism produce higher levels of the IRF5 transcript.⁵³

Other susceptibility genes have been identified in primary Sjögren's syndrome, but the findings have not yet been widely replicated. In a case-control study, an increased risk for primary Sjögren's syndrome was associated with a variant haplotype of the transcription factor Signal Transducers and Activator of Transcription 4 (STAT4).⁵⁴ This STAT4 polymorphism has also been shown to increase the risk for systemic lupus erythematosus and rheumatoid arthritis. STAT4 is a key intracellular signaling molecule involved in IL-12 and IL-23 signaling and is known to promote the development of T helper 1 (Th1) and T helper 17 (Th17) responses. Polymorphisms in the STAT4 and IRF5 genes appear to be additive in the risk for developing primary Sjögren's syndrome.⁵⁵ In other studies, Nordmark and colleagues⁵⁶ have identified three gene loci associated with an increased risk of primary Sjögren's syndrome—the early B cell factor (EBF1) gene, the interval encompassing family with sequence similarity 167 member A and B lymphoid tyrosine kinase (FAM167A-BLK), and the tumor necrosis family member 4 (TNFSF4, or the OX40L gene). All three genes are involved in B cell development, which is of particular interest due to the hyperactivated state of B cells in this disease.

The human genome contains conserved noncoding elements with functional sequences including regulatory motifs in promoters and untranslated regions of genes. Some of these conserved noncoding elements encode microRNAs, a novel means for regulation of gene expression. MicroRNAs influence both innate and adaptive immunity and have been shown to play a role in late B cell differentiation and development, as well as the establishment of B cell tolerance. Early studies have shown that microRNA expression patterns in salivary gland tissue can

Table 73-2 Mouse Models of Sjögren's Syndrome*

Mouse Model	Phenotype	Comments
Spontaneous Disease Models		
(NZB)NZW F1 mice MRL/ <i>lpr</i>	Progressive focal sialadenitis Lymphocytic infiltration of lacrimal and salivary glands; anti-Ro/SS-A and MR3 antibodies; oligoclonal expansion of T cells and IgA and IgM production in the salivary glands	Glandular involvement F > M Normal secretory function; mRNAs for IL-1 and TNF expressed in salivary glands before onset of sialadenitis
NOD and its derivatives NOD.H2h4, NOD.Q, and NOD.P, NOD.E2f ^{-/-} , NOD. <i>scid</i>	Lymphocytic infiltration of lacrimal and salivary glands; NOD.H2h4 strain (but not parental NOD strain) secretes high levels of anti-Ro/SS-A and anti-La/SS-B antibodies; reduced glandular function	Mice also develop diabetes; exchange of H2 haplotype from H2g7 to H2q (NOD.Q) or H2p (NOD.P) does not affect the frequency of sialadenitis; disruption of ICA69 locus prevents lacrimal gland inflammation and reduces salivary gland inflammation; NOD IFN- γ ^{-/-} mice do not develop glandular disease; blockade of LT- β R signaling pathway reduces salivary gland infiltrates and improves salivary gland function
NFS/ <i>sld</i>	Lymphocytic infiltration of lacrimal and salivary glands; anti- α -fodrin antibodies	Aberrant immune responses to α -fodrin; mice develop autoimmune lesions in other organ systems
Experimentally Induced Models		
Carbonic anhydrase (PL/J mice)	Lymphocytic infiltration of salivary glands; antibodies to carbonic anhydrase	Disease induction requires multiple injections of peptide emulsified in Freund's adjuvant
Ro peptides (Balb/c mice)	Lymphocytic infiltration of salivary glands; glandular hypofunction, anti-Ro/SS-A and anti-La/SS-B antibodies	
Transgenic or Knockout Models		
Id3 ^{-/-}	Lymphocytic infiltration of lacrimal and salivary glands; adoptive transfer experiments; anti-Ro/SS-A and anti-La/SS-B antibodies; salivary hyposecretion	Id3 gene involved in TCR-mediated T cell indicate a role for T cells in the development of disease; treatment with anti-CD20 antibodies ameliorates disease
PI3K ^{-/-}	Lymphocytic infiltration of the lacrimal glands; anti-Ro/SS-A and anti-La/SS-B antibodies	No anti-Ro/SS-A or anti-SS-B antibodies; also develop lupus manifestations and anti-DNA antibodies and RF
BAFF transgenic	Lymphocytic infiltration of lacrimal and salivary glands; unique population of marginal zone B cells in salivary glands	
IL-14 α transgenic	Lymphocytic infiltration of lacrimal and salivary glands; hypergammaglobulinemia; <25% of animals develop anti-Ro/SS-A and anti-La/SS-B antibodies; glandular hyposecretion; mild immune complex-mediated renal disease and lymphocytic interstitial pneumonitis	IL-14 is a growth factor for B cells; mice develop large B cell lymphomas later in life; role for LT- α in the salivary gland inflammation; infiltrate primarily B cells with relatively few CD4 ⁺ and CD8 ⁺ T cells
IL-12 transgenic	Lymphocytic infiltration of lacrimal and salivary glands; anti-La/SS-B antibodies; glandular hyposecretion; increased acinar cell volume	Mice also develop thyroiditis and lung pathology

*See references 58 and 59 for further details.

BAFF, B cell activating factor; F, female; ICA69, islet cell antigen 69; Id3, protein inhibitor of DNA binding 3; IFN- γ , interferon- γ ; IL-1, interleukin-1; LT- α , lymphotoxin- α ; LT- β R, lymphotoxin β receptor; M, male; MR3, muscarinic receptor subtype 3; NOD, nonobese diabetic; NZB/NZW F1, New Zealand Black \times New Zealand White F1 (mouse hybrid); PIK3, phosphoinositide 3-kinase; TNF, tumor necrosis factor.

distinguish patients with Sjögren's syndrome from controls, suggesting a pathologic role for dysregulated microRNA expression in the regulation of the chronic inflammatory response.⁵⁷

Epigenetics refers to the study of inherited changes in gene expression caused by mechanisms other than a change in DNA sequence of that gene. Its principal mechanisms include remodeling of chromatic structure by DNA methylation and histone modification. Thus far, virtually nothing is known about the epigenetics of primary Sjögren's syndrome.

Many insights have been gained about disease mechanisms in primary Sjögren's syndrome from studies of humans with this autoimmune disease, as well as animal models. Experiments in model systems enable hypotheses to be examined in ways not possible in humans and

have contributed to understanding the immunoregulatory disturbances underlying the clinical expression of disease (Table 73-2).^{58,59} Whereas these animal models have shed light on disease mechanisms, it has been possible to perform highly significant research in humans with primary Sjögren's syndrome because of the accessibility of labial salivary gland tissue for immunohistopathologic analysis. Studies of labial salivary gland biopsies from patients with this disease have shown approximately 90% of the infiltrating cells are composed of CD4⁺ T lymphocytes and B lymphocytes, with the remainder an admixture of plasma cells, CD8⁺ T cells, FoxP3⁺ T regulatory cells, CD56⁺ natural killer (NK) cells, and macrophages, as well as myeloid and plasmacytoid dendritic cells (DCs)⁶⁰ (Figure 73-1). Most of the infiltrating T cells bear the memory phenotype (CD45RO) and display a restricted T cell receptor (TCR) repertoire representing

Figure 73-1 Histopathology of the labial salivary gland in primary Sjögren's syndrome. **A**, Hematoxylin-eosin (H&E) staining (4 \times). **B**, H&E staining (20 \times). **C**, Anti-CD3 staining of T cells. **D**, Anti-CD21 staining of B cells. Mononuclear cells aggregate in foci throughout the gland in a periductal distribution (**A** and **B**). In this biopsy, most of the mononuclear cells are T cells (**C**) and the minority are B cells (**D**).

several different clonotypes across multiple V β families. The proportion of B cells in the infiltrate increases with the severity of the inflammatory lesion.

The infiltrating mononuclear cells tend to coalesce around ducts and blood vessels, and in more severe inflammatory lesions they may form aggregates organized into germinal center (GC)-like structures. The GC-like structures display well-circumscribed mononuclear cell infiltrates with B and T cell components, Ki-67⁺ proliferating cells, CD21/CD35⁺ follicular DC networks, and CD31⁺ high endothelial venules (HEVs).⁶¹ CXCL13 expression by epithelial cells, HEVs, and within germinal center-like structures together with the expression of CXCL12 and CCL21 provides a salivary gland microenvironment capable of attracting and retaining B cells.⁶²⁻⁶⁴ The myeloid DCs and macrophages, the classic antigen-presenting cells, are mostly found in proximity to the ductal epithelium, where they have been shown to secrete tumor necrosis factor (TNF), interleukin-6 (IL-6), IL-10, IL-12, and IL-18. Minor salivary glands also contain a small number of plasmacytoid DCs, the main producers of the type I IFNs.⁶⁵ A robust type I IFN signature has been detected both in the salivary glands and peripheral blood of patients with primary Sjögren's syndrome.^{65,66} The generation of type I IFNs by plasmacytoid DCs, among the

first lines of defense against viral infection, is partially dependent on signals through TLR7 and TLR9.

The analysis of T cell cytokines in labial salivary gland biopsies from patients with primary Sjögren's syndrome suggests a predominantly Th1- and Th17-driven response.⁶⁷ Studies of the expression of cytokine messenger RNAs (mRNAs) in salivary gland tissue show mainly upregulation of IL-2 and IFN- γ , the Th1-specific cytokines, and lesser quantities of IL-4, IL-5, and IL-13, the Th2-specific cytokines. Th17 cells, so named because they produce IL-17, are also found in the minor salivary glands; the salivary gland microenvironment is also rich in transforming growth factor (TGF)- β , IL-6, and IL-23, which are cytokines known to promote the development of this subset.⁶⁸ In addition, the salivary gland infiltrates contain a generous infiltrate of FoxP3⁺ regulatory T cells.⁶⁹ These cells typically show suppressive behavior, but as yet they have an uncertain role in regulating the chronic inflammatory lesion.

Several features of primary Sjögren's syndrome implicate B cells in disease mechanisms. B cells are the source of autoantibodies, but they also activate T cells through their ability to present antigen, are stimulated to secrete proinflammatory and anti-inflammatory cytokines, and facilitate the organization of secondary and tertiary lymphoid tissue.

The frequent presence of hypergammaglobulinemia, circulating immune complexes, mixed monoclonal immunoglobulin M (IgM) cryoglobulinemia, and serum autoantibodies in patients with primary Sjögren's syndrome implies B cells are in a dysregulated state. Most B cells in the salivary gland tissue exhibit a memory phenotype, express somatically hypermutated immunoglobulin V genes, and show preferential changes in V_L gene usage and the length of CDR3 from V_H gene rearrangements, which are findings characteristic of an antigen-driven response.⁷⁰ Salivary gland B cells appear to be responding specifically to antigen, although the site of antigen encounter and activation (salivary gland vs. secondary lymphoid tissue) remains uncertain. Germinal center-like structures found in some of the salivary gland biopsies provide an opportune environment for the selection and differentiation of antigen-driven B cell responses. The distribution of peripheral blood B cell subsets in primary Sjögren's syndrome differs from healthy controls, showing increased proportions of CD27⁻ (naïve) B cells and decreased proportions of CD27⁺ (memory) B cells.⁷¹ Among several possibilities, these changes in the peripheral blood may result from abnormal trafficking of CD27⁺ memory B cells to the target tissues, aberrations in B cell development, or both.

Several intrinsic B cell defects have also been found in patients with primary Sjögren's syndrome including abnormal retention of preswitch Ig transcripts in circulating post-switch CD27⁺ memory B cells⁷² and enhanced B cell signaling due to altered kinetics of B cell receptor translocation to lipid rafts.⁷³ Moreover, studies in patients with primary Sjögren's syndrome have shown increased serum and salivary gland tissue levels of B cell activating factor (BAFF), a B cell prosurvival factor,⁷⁴ as well as upregulated salivary gland expression of lymphotoxin (LT)- β mRNA.⁷⁵ LT- β is required for the formation of lymph nodes and germinal centers, while the heterodimer LT- α /LT- β can induce the development of ectopic germinal center-like structures. LT- α in soluble form induces the secretion of IFNs and chemokines, which are elevated in the salivary gland tissue from patients with primary Sjögren's syndrome. Levels of IL-14, another B cell growth factor, also appear to be increased in the serum and saliva of patients with primary Sjögren's syndrome.⁷⁶ IL-14 transgenic mice have been shown to develop a Sjögren's-like phenotype⁷⁷ in which the local tissue response is critically dependent on LT- α .⁷⁸ Blocking LT- β receptor signaling in NOD mice ablates the lymphoid organization in the salivary glands and improves their function,⁷⁹ further evidence that LTs may play a role in the pathogenesis of Sjögren's syndrome. Finally, abnormal B cell behavior is implied in primary Sjögren's syndrome by the predisposition of this disease toward the development of non-Hodgkin's B cell lymphoma. Interestingly, IL-14 transgenic mice develop large B cell lymphomas later in life.⁷⁷

Anti-Ro/SS-A and anti-La/SS-B antibodies do not appear to have a pathogenic role in disease mechanisms despite their diagnostic and prognostic significance. The stimulating antigen(s) is unknown. An aberrant response to self may be provoked by altered expression of autoantigens. Several models have been proposed to explain the altered expression of autoantigens including differential expression of protein isoforms, post-translational modification, and

abnormal autoantigen presentation via apoptotic blebs, exosomes, or heat shock protein-mediated cross-priming.⁸⁰ Ro/SS-A and La/SS-B proteins do in fact show upregulated expression in the vicinity of the immunopathologic lesion in primary Sjögren's syndrome,⁸⁰ where they may induce local immune responses. Saliva from patients with this disease has been shown to contain anti-Ro/SS-A and anti-La/SS-B antibodies.⁸¹ Although this finding may be interpreted to reflect local production of autoantibodies, it may also reflect extravasation of proteins from blood vessels into the inflamed tissues.

Among the other autoantibody specificities, those directed against the muscarinic receptor (MR) have attracted the most interest because of their possible role in causing glandular hypofunction. The MR family of receptors is bound by acetylcholine, which mediates the effects of the preganglionic and postganglionic parasympathetic nerve fibers that primarily regulate salivary flow. The muscarinic type 3 receptor (M3R), the target of autoantibodies in primary Sjögren's syndrome, is the subtype that predominately controls salivary flow. Two lines of evidence support the hypothesis that anti-M3R antibodies reduce exocrine gland function. Firstly, serum immunoglobulins from patients with primary Sjögren's syndrome have been shown to bind M3R receptors on acinar cell membranes; they also have been shown to inhibit acetylcholine-evoked Ca^{2+} responses in a salivary gland cell line.⁸² This Ca^{2+} -sensitive response is tightly regulated through intracellular signaling pathways that open the Cl^- channels on the apical membrane, resulting in an osmotic gradient and movement of water into the duct lumen. Secondly, passive transfer of the antibody has been shown to cause glandular hypofunction in NOD mice, an animal model of Sjögren's syndrome.⁸³ However, the assays for detecting serum anti-M3R antibodies have produced variable results depending on the methodology. For this reason, it has been difficult to determine the diagnostic sensitivity and specificity of serum anti-M3R antibodies in primary Sjögren's syndrome and the possible relationship of these autoantibodies to glandular hypofunction. Other autoantigens have been identified in patients with primary Sjögren's syndrome including α -fodrin, poly(ADP)ribose polymerase, carbonic anhydrase, and ICA69 protein. Despite initial enthusiasm for the possible etiologic role of α -fodrin in primary Sjögren's syndrome, recent studies have shown that serum anti- α -fodrin antibodies are not highly specific for this diagnosis.⁸⁴ Autoantibodies to carbonic anhydrase, poly(ADP)ribose polymerase, and ICA69 protein occur in only a minority of patients with primary Sjögren's syndrome and therefore do not appear to be attractive candidates for the initiating autoantigens.

In primary Sjögren's syndrome, the glandular epithelial cell appears to be an active participant in the abnormal immune response. In the salivary gland, the mononuclear cells preferentially congregate around ductal epithelium. The epithelial cells show upregulated expression of HLA class I and II molecules; adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1; CD54), vascular cell adhesion molecule-1 (VCAM-1; CD106) and E-selectin; and co-stimulatory molecules such as CD80 and CD86⁸⁵; they also produce high levels of cytokine mRNAs for IL-1, IL-6, IL-12, IL-18, and TNF,⁸⁶⁻⁸⁸ as well as BAFF.⁷⁴ Ductal epithelial cells have also been shown to express

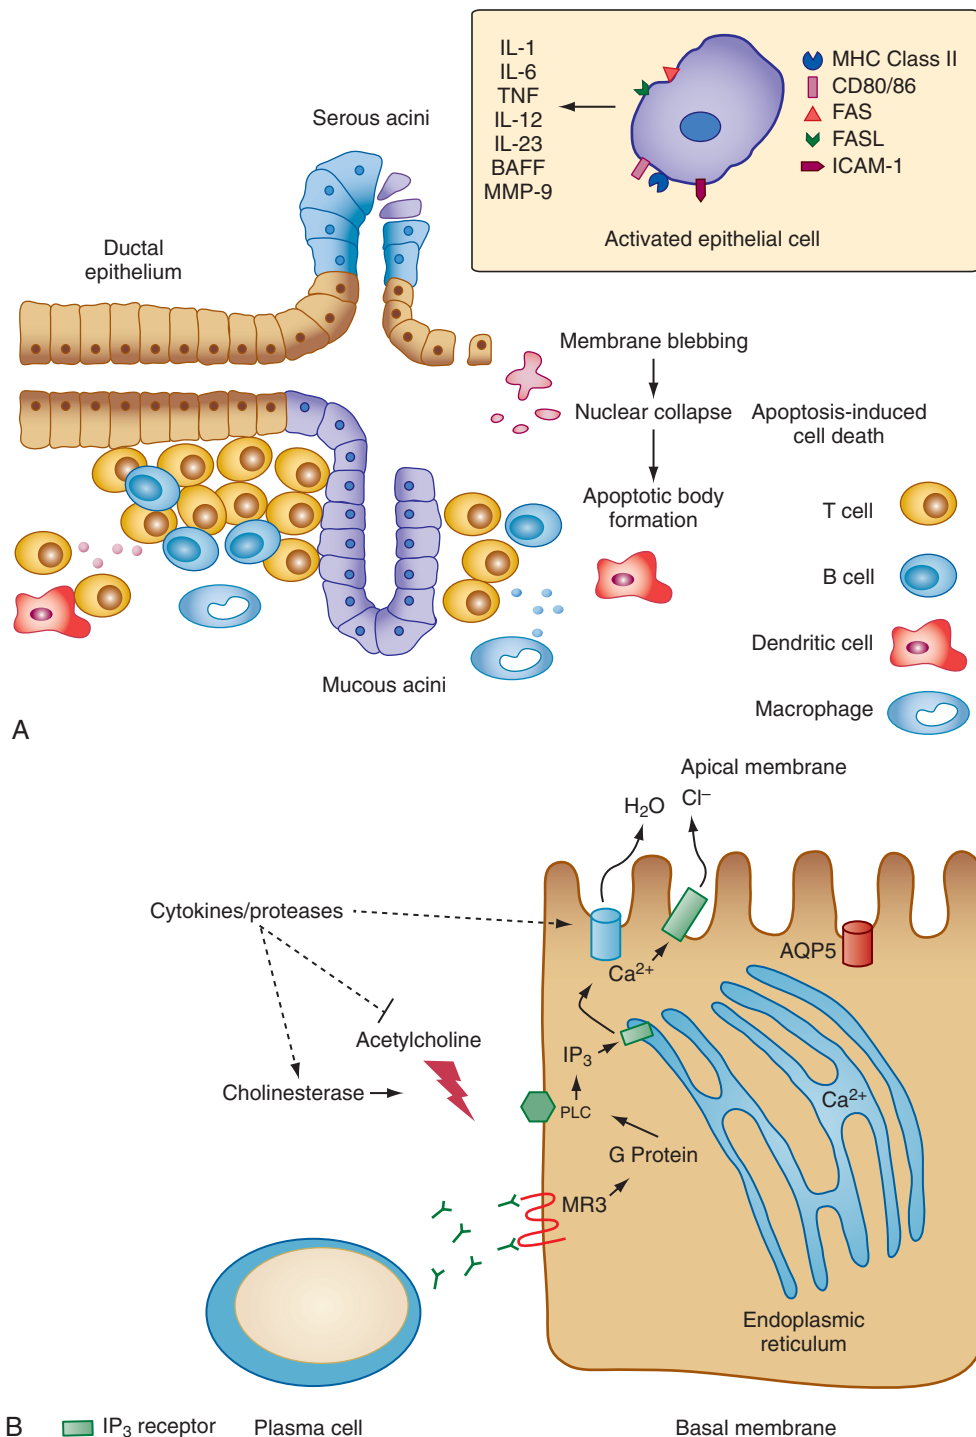

Figure 73-2 Two models for the pathogenesis of salivary gland inflammation in Sjögren's syndrome. **A**, Glandular hypofunction is explained by tissue loss secondary to immune attack, resulting in cytotoxic cell death and apoptosis. Epithelial cells likely play a central role in this process by several mechanisms: antigen-presentation and T cell activation; production of proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, tumor necrosis factor (TNF), IL-12, and IL-23; and secretion of proteases. Epithelial cells also upregulate expression of Fas (FAS) and Fas ligand (FASL), cell surface molecules involved in the activation of apoptotic pathways. Other immune cells such as T cells, B cells, macrophages, and dendritic cells serve to amplify the chronic inflammatory response. In model **B**, glandular hypofunction results from downregulation of receptor-mediated secretion of salivary fluid into the ductal lumen. Acetylcholine binds to muscarinic receptor type 3 (MR3) on the surface of acinar cells, stimulating production of the second messenger inositol 1,4,5-triphosphate (IP₃). IP₃ in turn diffuses through the cytoplasm until it binds its receptor, IP₃R, on the endoplasmic reticulum. This interaction causes calcium to be released into the cytoplasm, which opens Ca²⁺-sensitive chloride channels on the apical membrane of the cell. Electrochemical neutrality is preserved when Na⁺ follows chloride across the membrane, while the osmotic gradient propels the water into the ductal lumen. Mechanisms of immune-mediated glandular hypofunction might include inhibition of acetylcholine release by cytokines, increased breakdown of acetylcholine in the epithelial space by upregulated production of cholinesterases, blockade of M3R by autoantibodies, inhibition of intracellular signaling pathways involved in the fluid secretory process, or altered expression of aquaporin 5 (AQP5), which appears to be primarily responsible for water movement through the apical cell membrane. See [reference 96](#) for more details. BAFF, B cell activating factor; ICAM-1, intercellular adhesion molecule-1; MHC, major histocompatibility complex; MMP-9, matrix metalloproteinase-9; PLC, phospholipase C.

mRNAs for several different proinflammatory chemokines including CXCL13, CCL17, CCL21, and CCL22.⁸⁹ Cultured salivary gland epithelial cells also express functional TLR3 and TLR7 molecules,^{90,91} endowing a capability to sense pathogens and endogenous molecules produced by injured tissues. Activated epithelial cells are likely driving the aberrant innate and adaptive immune responses not only in the lacrimal and salivary glands but also in the lungs and kidneys, as well as other extraglandular sites.

At least two models exist to explain the glandular hypofunction in Sjögren's syndrome. In one model, it may be hypothesized that the glandular tissue is destroyed by an immune onslaught perpetuated by persistent exposure to self-antigens or other environmental stimulants (e.g., viral infection), leading to apoptosis of acinar epithelial cells and the irreversible loss of salivary gland function⁹² (Figure 73-2A). A weakness of this model is that studies suggest epithelial cells rarely undergo apoptosis in the salivary gland tissue despite the fact they upregulate expression of mediators of cell death such as Fas, Fas ligand, and Bax (B cell lymphoma 2-associated X protein).⁹³ Ligand binding to CD40 expressed on epithelial cells in the salivary gland tissue also leads to Fas-mediated cell death by down-regulating c-FLIP (cellular FLICE-like inhibitor protein), an inhibitor of Fas-mediated cell death.⁹⁴ Because no studies have yet shown that an imbalance truly exists between the rates of glandular proliferation and damage, the relevance of this model to glandular hypofunction is uncertain. It also does not explain why many patients with markedly diminished salivary flow retain substantial amounts of normal-appearing acinar tissue in their salivary glands.⁹⁵

A second model⁸⁶ assumes apoptosis is not a significant factor in the loss of acinar epithelium and instead posits that glandular function is *inhibited* (and not destroyed) by immune-mediated mechanisms (Figure 73-2B). This model implies a reversibility component to the loss of salivary flow and a pathologic process interrupting M3R activation. Possible mechanisms for such inhibitory effects include a reduction in acetylcholine release, increased breakdown of

acetylcholine in the epilemmal space (e.g., acetylcholine must diffuse 100 nm from its release point at the nerve ending to the receptor on the cell), and blockade of M3R by antibodies.⁹⁶ Relatively little direct evidence supports any of these mechanisms except for the experiments showing that anti-M3R antibodies may block receptor function. Nevertheless, it is possible that the cytokine milieu in the inflamed glandular tissue interferes with the mechanisms controlling acinar gland function. In the NOD mouse, for example, impairment of salivary gland secretion does not appear to be readily explained by the destruction of acinar glands.⁹⁷ Regardless, the “immune destructive” and “immune inhibited” models are not mutually exclusive and may contribute to glandular hypofunction at various stages of the disease.

CLINICAL FEATURES

Keratoconjunctivitis Sicca

Chronic inflammation of the lacrimal glands diminishes secretion of aqueous tears, which if severe, may destroy the conjunctival and bulbar epithelium. Aqueous tear deficiency produces a dry eye, causing symptoms of grittiness or foreign body sensation, burning, photophobia, and eye fatigue. Routine eye examination usually reveals a reduction in the tear flow, as measured by the Schirmer-I-test. Additional findings may include the absence of tears in the conjunctival sac and dilated bulbar conjunctival vessels. Thick mucus may also be seen in the inner canthus of the eye. Slit-lamp examination allows for more detailed visualization of the corneal and conjunctival surface. Following instillation of lissamine green dye or fluorescein onto the ocular surface, slit-lamp examination may expose devitalized cells or epithelial defects, respectively, signs of corneal and conjunctival damage. Severe dryness may result in corneal abrasion or ulceration.

The anatomy of the tear film informs the differential diagnosis of a dry eye (Table 73-3). The tear film consists

Table 73-3 Differential Diagnosis of Primary Sjögren's Syndrome

Condition	Associated Clinical/Radiologic/Pathophysiologic Features	Immunologic/Histopathologic Profile
Dry Eye (Keratoconjunctivitis Sicca)		
Aqueous Tear Deficiency (Failure of Lacrimal Tear Secretion)		
Sarcoidosis*	Lacrimal and parotid gland enlargement, cervical and hilar adenopathy, ILD, uveitis, arthralgia/arthritis, erythema nodosum	ANA negative or low titer; noncaseating granulomas in multiple organs (e.g., lymph nodes, lungs, spleen, liver, skin, salivary glands)
Chronic hepatitis C infection	Chronic hepatitis	Serum hepatitis C virus antibodies; hepatitis C viremia
Chronic GVHD	Occurs after allogeneic hematopoietic stem cell transplantation; other ocular features include sterile conjunctival inflammation and scarring, with progressive loss of goblet cells and dysfunction of meibomian glands	Lacrimal gland fibrosis, with mild chronic inflammation
Sensory block	Corneal surgery (LASIK), contact lens wear, diabetes	
Motor block	Cranial nerve VII damage	
Age-related	None	
Systemic drugs†		

Continued

Table 73-3 Differential Diagnosis of Primary Sjögren's Syndrome—cont'd

Condition	Associated Clinical/Radiologic/Pathophysiologic Features	Immunologic/Histopathologic Profile
Evaporative (Excessive Water Loss from the Ocular Surface)		
Meibomian gland deficiency	Ocular redness and burning; increased tear break-up time and tear hyperosmolarity; secondary to posterior blepharitis, acne rosacea, seborrheic dermatitis, and drugs (e.g., retinoids)	
Cicatricial pemphigoid [†]	Scarring of the meibomian orifices, loss of goblet cells	
Poor lid congruity or low blink rate	Proptosis (poor lid congruity), Parkinson's disease (low blink rate)	
Vitamin A deficiency	Impaired goblet cell development	
Dry Mouth (Hyposalivation)		
Amyloidosis	Nephrotic syndrome	ANA negative; monoclonal gammopathy; biopsy often shows amyloid deposits
Hemachromatosis	Cirrhosis	Labial salivary gland biopsy with heavy hemosiderin deposits in the ductal epithelium and loss of acinar glands
Chronic GVHD	Salivary gland dysfunction less common than lacrimal gland dysfunction; may be associated with oral mucosal involvement of chronic GVHD	Periductal inflammation, fibrosis, and glandular atrophy
Chronic hepatitis C infection	See above	Labial salivary gland biopsy shows chronic inflammation similar to that of Sjögren's syndrome
Diabetes mellitus	Type I or type II diabetes	
Radiation therapy	Side effects after radiotherapy for head and neck cancer	Lack of functional acinar cells; damage to ducts, blood vessels, and nerves
Anxiety		
Systemic drugs [‡]		
Parotid Gland Enlargement		
Sarcoidosis*	See above	See above
IgG4-related diseases	Multiorgan involvement: lacrimal and salivary gland enlargement, chronic sclerosing sialadenitis, autoimmune pancreatitis, sclerosing cholangitis, lung nodules, interstitial pneumonitis, aortitis, interstitial nephritis, prostatitis, orbital pseudotumor, dacryoadenitis, meningitis, hypophysitis	High serum IgG4 levels; lymphoplasmacytic infiltrate and abundance of IgG4 ⁺ plasma cells in tissues
Multicentric Castleman's disease	Lacrimal and salivary gland enlargement (uncommon); fever, lymphadenopathy, hepatomegaly, edema, and ascites (common); increased incidence of non-Hodgkin's lymphoma	Elevated serum IL-6 levels; some patients with increased serum IgG4 levels; lymph node biopsy shows interfollicular plasmacytosis
Diabetes mellitus	More common in type II than type I diabetes	Sialadenitis
Alcoholism		Sialadenitis
HIV lymphoepithelial lesion	Bilateral involvement	Extensive lymphoid infiltrate with reactive germinal centers (CD8 > CD4 ⁺ T cells)
Benign tumors	Painless swelling of the parotid gland; usually unilateral but sometimes bilateral	Pleomorphic adenoma (usually unifocal); Warthin tumor: often multifocal and bilateral; oncocytoma; many other types
Malignant carcinoma	Painless swelling of the parotid gland, facial nerve palsy	Most common: mucoepidermoid carcinoma, acinic cell carcinoma, adenoid cystic
Primary B cell lymphoma	Unilateral or bilateral parotid gland swelling	Marginal zone B cell lymphoma most common subtype (also called <i>MALT-type</i>); follicle center and mantle zone lymphomas may also occur in this region; diffuse large B cell lymphoma (rare)
Primary T cell lymphoma	Rarely may present as a parotid gland mass; HTLV-1-associated	Anaplastic large cell or diffuse pleomorphic (medium and large cell)
Calculus duct obstruction	Painful enlargement of salivary glands	Ruptured ducts and obstructive granulomas

*May coexist with primary Sjögren's syndrome.

[†]Common offending drugs include: anticholinergics (e.g., antihistamines, tricyclic antidepressants, antispasmodics), clonidine, diuretics, isotretinoin, estrogen replacement therapy, amiodarone.[‡]May also destroy the lacrimal gland and cause lacrimal duct obstruction late in the clinical course.

ANA, antinuclear antibodies; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; HTLV-1, human T lymphotropic virus type 1; IL-6, interleukin-6; ILD, interstitial lung disease; MALT, mucosa-associated lymphoid tissue.

of three major layers: the outer lipid layer, the middle aqueous layer, and the inner mucin layer. In addition to Sjögren's syndrome, conditions associated with infiltration of the lacrimal glands (e.g., sarcoidosis) and diminished tear flow (e.g., medications, aging, and estrogen deficiency) may decrease aqueous tear flow. The lipid layer derives from the meibomian glands and traps the aqueous tear film on the eyeball and protects it from rapid evaporation. Meibomian gland dysfunction, or posterior blepharitis, produces dry eyes from rapid evaporation of tears; it may be present with aqueous tear deficiency and be an aggravating factor in patients with keratoconjunctivitis sicca. Meibomian gland dysfunction is often associated with ocular rosacea and seborrheic dermatitis, two conditions encountered often in clinical practice that lead to symptoms of dry eyes. Lipid degradation resulting from meibomian gland inflammation may produce free fatty acids, which are irritating to the ocular surface and may cause punctate keratopathy. The mucin layer originates from the goblet cells of the conjunctiva and, if deficient, leads to an uneven distribution of the tear film over the surface of the eye. Vitamin A deficiency and Stevens-Johnson syndrome are examples of conditions associated with an abnormal mucin layer.

Xerostomia

The changes in the quality and quantity of the saliva are responsible for the signs and symptoms of xerostomia. Although symptoms of dry mouth are relatively common in the general population, they are usually more severe in Sjögren's syndrome and cause incessant difficulties with chewing and swallowing dry food, altered taste (metallic, salty, or bitter), and prolonged speaking. Patients with xerostomia may have problems wearing dentures. Despite complaints of a dry mouth, many patients will appear to have a normal oral examination owing to residual salivary flow. Others with more severe hypofunction will manifest a dry, sticky, or erythematous oral mucosa.

Two complications of xerostomia are important to the care of patients with xerostomia, especially those with severe deficits in salivary flow. Xerostomia often results in rampant dental caries, cracked teeth, and loose fillings. Oral candidiasis, the other frequent complication, typically manifests as the atrophic variant, which is characterized by erythema and atrophy of the oral mucosa and filiform papillae on the dorsum of the tongue, with angular cheilitis. Sometimes, a thin, white exudate may appear on the surface of the tongue. The "thrushlike" variant of oral candidiasis is seen much less frequently in patients with xerostomia except in the face of recent antibiotic therapy.

About one-quarter of patients with primary Sjögren's syndrome suffers enlargement of the parotid or submandibular glands during the course of their disease. Chronic swelling is usually painless and may be unilateral or bilateral; it is often diffuse and firm by palpation. Transiently painful episodes of acute swelling and tenderness may also punctuate the clinical course. Acute swelling of the major salivary glands probably results most often from dried mucus obstructing the lumens of the major ducts; it usually subsides within a few days with conservative therapy. Rarely, bacterial infections may cause acute salivary gland swelling and should be considered as a possible etiology if the patient has a fever or

other constitutional complaints. Asymmetric gland enlargement with palpable hard nodules that are increasing in size may indicate a neoplasm such as a lymphoma.

Involvement of Other Exocrine Glands

Glandular hypofunction may also affect the nasal passages (meatal obstruction from dried mucus), larynx (hoarseness), trachea (cough), vagina (dyspareunia), and skin (pruritus), producing symptoms of dryness. Virtually any exocrine gland may be involved in this disease.

Extraglandular Manifestations

Nearly three-quarters of patients with primary Sjögren's syndrome manifest signs or symptoms of extraglandular disease. Extraglandular involvement is more likely to occur in patients with serum anti-Ro/SS-A and anti-La/SS-B antibodies, as well as hypergammaglobulinemia, cryoglobulinemia, and hypocomplementemia. However, only about 25% of patients with primary Sjögren's syndrome develop moderate or severe extraglandular disease.

Fatigue, a complex and multifaceted phenomenon, occurs in approximately 70% of patients with primary Sjögren's syndrome.⁹⁸ It is also a symptom of depression, chronic anxiety, fibromyalgia, and sleep deficit, as well as a side effect of certain medications. The United Kingdom Sjögren's Interest Group has developed an instrument called the Profile of Fatigue and Discomfort–Sicca Symptoms Inventory (PROFAD-SSI) to specifically measure both somatic (needing rest, poor starting, low stamina, weak muscles) and mental fatigue (poor concentration, poor memory) in this disease.⁹⁹ In 547 patients with a confirmed diagnosis of primary Sjögren's syndrome, somatic fatigue was the dominant predictor of physical function and general health.¹⁰⁰ The relative contribution of behavioral and cognitive variables to fatigue was studied in 94 patients with primary Sjögren's syndrome.¹⁰¹ Although depression was associated with higher levels of fatigue in this study, it was not present in most patients who reported fatigue. The link between fatigue and "biologic disease activity" is not fully understood in primary Sjögren's syndrome. Increased serum cytokines such as IL-6 and type I IFNs, as well as neuroendocrine and autonomic dysfunction are postulated to be contributing factors to the physical and mental aspects of fatigue in this setting.⁹⁸

Raynaud's syndrome has been reported in 13% to 33% of patients with primary Sjögren's syndrome, often preceding the onset of sicca symptoms by several years.¹⁰² Digital ulcers occur only rarely.

Among the dermatologic manifestations, the most common are xerosis, or dry skin; eyelid dermatitis; and angular cheilitis. In addition, many patients develop a variety of other cutaneous manifestations including annular erythema, purpura, and urticarial vasculitis. Annular erythema has been described in several forms: a donut-ring-like erythema with an elevated border (type I); a subacute cutaneous lupus erythematosus (SCLE)-like lesion with marginally scaled polycyclic erythema (type II); and a papular insect bite-like erythema (type III).¹⁰³ Histopathologically, these lesions are characterized by a deep perivascular lymphocytic infiltrate without the epidermal changes associated with lupus.¹⁰⁴ In

some cases, immunoglobulin and complement deposition is observed along the basement membrane with liquefaction degeneration in the basal layer of the involved skin. The type I lesion appears to be specific for primary Sjögren's syndrome, occurring predominantly in Asian but not Western populations.

Cutaneous vasculitis may be expressed in several different forms including palpable purpura, erythematous papules or macules, and ulcers, with lesions predominantly located in the lower limbs.¹⁰⁵ Such lesions are frequently accompanied by other extraglandular manifestations of disease such as arthritis, peripheral neuropathy, Raynaud's syndrome, anemia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, serum rheumatoid factor, and serum anti-Ro/SS-A and anti-La/SS-B antibodies. In one study, 27% and 50% of the cases of small vessel, cutaneous vasculitis were present with and without cryoglobulinemia, respectively; 21% of cases were classified as *urticarial vasculitis*.¹⁰⁵ Livedo reticularis has also been described in this setting.

Polyarthralgia occurs frequently in patients with primary Sjögren's syndrome. In a retrospective study, articular symptoms in primary Sjögren's syndrome had a prevalence rate of 45%.¹⁰⁶ Although most patients complain only of polyarthralgia, a subset may develop objective signs of synovitis, which is nonerosive, symmetric, and polyarticular of waxing and waning intensity. Joint symptoms may precede the diagnosis of primary Sjögren's syndrome in up to one-third of cases.¹⁰⁷ In two separate studies, anticyclic citrullinated peptide (anti-CCP) antibodies were detected in serum from 7.5% and 9.9% of patients with primary Sjögren's syndrome.^{108,109} However, in only one of these studies was their presence closely associated with synovitis,¹⁰⁹ and in neither study did it appear that serum anti-CCP positivity was associated with radiographic erosions or progression to rheumatoid arthritis.

Involvement of the airways and lung parenchyma in primary Sjögren's syndrome may take several forms including xerotrachea and xerobronchitis; nonspecific interstitial pneumonitis (NSIP); lymphocytic interstitial pneumonitis (LIP), now considered to be a subset of NSIP; usual interstitial pneumonitis (UIP); bronchiolitis; and lymphoma (reviewed in [reference 110](#)). The estimated prevalence of pulmonary involvement in primary Sjögren's syndrome varies depending on the thoroughness of the evaluation. In one study involving 123 patients with primary Sjögren's syndrome, 11.4% showed pulmonary signs or symptoms and/or impaired pulmonary function with abnormal chest computed tomography (CT) findings at the time of evaluation.¹¹¹

Evidence of small airways dysfunction is found often in asymptomatic patients with normal radiologic studies. In symptomatic patients, NSIP appears to be the predominant type of lung involvement. The diagnosis can often be made on the basis of clinical presentation, pulmonary function tests (PFTs), and abnormal chest CT findings. PFTs in patients with NSIP show a restrictive pattern with reduced diffusion capacity of lung carbon monoxide (DLCO). Chest CT scans in this condition reveal ground-glass opacities and a reticular nodular pattern. Bronchoalveolar lavage (BAL), which is not usually required for diagnosis, shows evidence of alveolar inflammation, with elevated neutrophil or

lymphocyte counts, or both. LIP is also associated with a restrictive pattern on PFTs. Chest CT findings are ground-glass opacities and thin-walled cysts, with centrilobular nodules, interlobular septal thickening, and bronchovascular bundle thickening ([Figure 73-3A](#)). Microscopically, the lung biopsy from patients with LIP shows a diffuse interstitial infiltrate composed of lymphocytes, plasma cells, and histiocytes, which expand the interlobular and alveolar spaces ([Figure 73-3B](#)). The PFTs in patients with UIP also show a restrictive pattern like NSIP and LIP, but the chest CT findings of lower lobe fibrosis, honeycombing, and traction bronchiectasis distinguish it from these other two types. Histopathologically, follicular bronchiolitis is

Figure 73-3 Lymphocytic interstitial pneumonitis (LIP) in a 44-year-old woman with primary Sjögren's syndrome. **A**, A slice through the lower lobes of a chest computed tomography scan showing diffuse ground-glass opacities, a scattering of multiple nodules in the periphery, and many thin-walled parenchymal cysts. **B**, Histopathologic examination from a wedge resection of the lower lobe of this patient shows a patchy, nodular interstitial infiltrate composed of mononuclear cells, with widening of the interlobular and alveolar spaces, consistent with LIP. (Reproduced with permission from ACP Medicine.)

characterized by nodular lymphocytic infiltrates with germinal center–like structures encircling respiratory bronchioles. PFTs in patients with bronchiolitis may show a restrictive or obstructive functional defect. The chest CT scan usually reveals reticulonodular infiltrates, but it may be normal in mild cases.

Lung biopsy can reveal evidence of not only interstitial lung disease but also other pathologic processes such as low-grade lymphoma or amyloidosis. Ito and colleagues¹¹² evaluated 33 patients with primary Sjögren's syndrome and biopsy-proven lung disease and found evidence of NSIP in 20 (61%), non-Hodgkin's lymphoma in 4 (12%), diffuse bronchiolitis in 4 (12%), and amyloid in 2 (6%). PFTs revealed restrictive changes in 19 (58%) patients and obstructive changes in 3 (9%) patients. Analysis of BAL fluid from 28 patients from this group was uniformly abnormal, showing elevated lymphocyte counts in 18 (64%) and elevated neutrophil counts in 19 (68%). In 31 patients, chest CT findings revealed an NSIP pattern in 14 (45%) and a UIP pattern in 4 (13%); 3 (10%) showed a pattern of organizing pneumonia. There were no cases of LIP in this series. By comparison, Parambil and colleagues¹¹³ evaluated 18 patients with biopsy-proven lung disease in association with primary Sjögren's syndrome and found a histopathologic pattern of NSIP in 5 (28%) patients, organizing pneumonia in 4 (22%) patients, UIP in 3 (17%) patients, LIP in 3 (17%) patients, lymphoma in 2 (11%) patients, and amyloid in 1 (6%) patient.

Renal disease is infrequently of clinical significance in primary Sjögren's syndrome. Tubular interstitial nephritis, type I renal tubular acidosis (RTA), glomerulonephritis, and nephrogenic diabetes insipidus have been reported in association with this disease. Tubular interstitial nephritis, which is characterized histopathologically by a peritubular lymphocytic infiltrate and fibrosis, rarely progresses to end-stage renal disease.^{114,115} A patient with primary Sjögren's syndrome has been described with tubular interstitial nephritis and acquired Gitelman's syndrome and tubular interstitial nephritis, with absence of a sodium-chloride cotransporter in the distal convoluted tubules.¹¹⁶ Rarely, severe potassium wasting from type I RTA can lead to muscle paralysis.¹¹⁷ Glomerular disease is exceedingly rare in this setting and may take several forms including membranous, membranoproliferative, mesangial proliferative, and focal crescentic glomerulonephritis.

Patients with primary Sjögren's syndrome have an increased frequency of gastrointestinal symptoms compared with the general population. Dysphagia and heartburn are particularly common complaints that may result from impaired salivary flow or esophageal motility, or both. About one-third of patients with primary Sjögren's syndrome have varying degrees of esophageal dysfunction, although many studies have been unable to correlate symptoms of dysphagia with a functional abnormality.¹¹⁸ The results of one study suggest that patients with primary Sjögren's syndrome do not have a primary disturbance of esophageal motility, but rather defective clearance of esophageal acid that exposes the esophageal lining to excessive amounts of acid, which in turn, produces morphologic changes and secondary dysmotility.¹¹⁹ Other results suggest parasympathetic dysfunction might be at the root of the esophageal abnormalities.¹¹⁸ A case has also been described of a patient with primary

Sjögren's syndrome who developed esophageal achalasia in the setting of a sensory ataxic neuropathy, which damaged the myenteric plexus and led to the esophageal abnormality.¹²⁰ In addition, chronic atrophic gastritis, which may cause dyspeptic symptoms, has been reported in a small number of cases of primary Sjögren's syndrome.¹²¹

Patients with primary Sjögren's syndrome may develop liver enzyme abnormalities for a variety of reasons, most often from an associated disorder such as hepatitis C virus infection, autoimmune hepatitis, primary biliary cirrhosis, or a nonspecific hepatitis.¹²² Bowel symptoms such as abdominal pain and constipation occur more commonly in patients with primary Sjögren's syndrome than healthy controls, but their etiology is often obscure.¹²³

Neurologic abnormalities are protean in primary Sjögren's syndrome, with varied patterns of peripheral and central nervous system involvement. The prevalence of central nervous system involvement that can be directly attributed to primary Sjögren's syndrome is likely to be in the range of 1% to 2%, but much higher rates have been reported with more liberal case definitions. For example, higher prevalence rates are noted when mood disturbances and minor cognitive and affective disturbances are included in the definition of central nervous system (CNS) involvement. Neuropsychiatric symptoms such as depression and minor cognitive disturbances occur in approximately one-third of patients with primary Sjögren's syndrome. However, they are nonspecific clinical disorders that occur frequently in the general population and in patients with other chronic diseases. Rarely, cases have been described in which patients with primary Sjögren's syndrome develop severe cognitive dysfunction. Brain magnetic resonance imaging (MRI) scans in these instances typically show nonspecific T2-weighted, high-intensity signals in the white matter that have an uncertain relationship to the clinical CNS findings. Focal CNS deficits have also been rarely described in patients with primary Sjögren's syndrome and include optic neuropathy, hemiparesis, movement disorders, cerebellar syndromes, recurrent transient ischemic attacks, and motor neuron syndrome.¹²⁴ Spinal cord syndromes resembling multiple sclerosis such as transverse myelitis and progressive myelopathy have also been reported in patients with primary Sjögren's syndrome.¹²⁵ Patients with primary Sjögren's have been described, too, with neuromyelitis optica in association with serum anti-aquaporin-4 antibodies.¹²⁶

Peripheral nervous system involvement is among the most common of the extraglandular features of primary Sjögren's syndrome. In a cross-sectional study, peripheral neuropathy was diagnosed in 17 (27%) of 62 patients with primary Sjögren's syndrome on the basis of a conventional neurologic examination.¹²⁷ However, only 34 (55%) in this group had abnormal nerve conduction velocity studies including 19 (31%) with a motor neuropathy, 8 (13%) with a sensory neuropathy, and 7 (11%) with a sensorimotor neuropathy. Some of the others with normal nerve conduction velocity studies may have had a small fiber neuropathy. Other peripheral neuropathies that have been reported in patients with primary Sjögren's syndrome are cranial neuropathies, autonomic neuropathies, and multiple mononeuropathies.¹²⁴ Most cases of peripheral neuropathy are dominated by sensory symptoms and typically do not progress to cause motor weakness.

Beyond lower extremity purpura, systemic vasculitis appears to be a rare manifestation of extraglandular disease. Patients can develop a small vessel vasculitis and cryoglobulinemia in the absence of hepatitis C virus infection and a medium-sized vessel vasculitis with features ranging from multiple mononeuropathies to ischemic bowel.

Lymphoma

Non-Hodgkin's lymphoma (NHL) is a complication of primary Sjögren's syndrome with important prognostic significance. In a recent study, the prevalence of NHL in this disease was 4.3%, with a median time of approximately 7.5 years from the diagnosis of primary Sjögren's syndrome to the development of NHL.¹²⁸ Several histopathologic types of NHL have been described in association with primary Sjögren's syndrome including marginal zone B cell lymphoma, follicular cell lymphoma, diffuse large B cell lymphoma, and lymphoplasmacytoid lymphoma. Marginal zone B cell lymphoma, which is a family of low-grade B cell lymphomas, is by far the predominant type of NHL associated with this chronic autoimmune disease.

The mucosa-associated lymphoid tissue (MALT) lymphoma, a type of marginal zone B cell lymphoma, occurs mostly in chronic autoimmune diseases such as primary Sjögren's syndrome. It develops at extranodal sites in relation to mucosae or glandular epithelium such as the lacrimal and salivary glands, lung, gastrointestinal tract, and skin. The earliest histopathologic feature of MALT lymphoma is the finding of monocytoid B cells surrounding the epithelium. Immunochemical staining of these lesions shows their clonality in revealing monotypic infiltrates of either Igκ- or Igλ-light chains.¹²⁸ With progression, these lesions show increasing proliferation of neoplastic cells, replacement of reactive follicles, and ductal dilatation. In primary Sjögren's syndrome, MALT lymphomas most often develop in the salivary glands, but they may also develop at other extranodal sites, especially the lung and gastrointestinal tract. In primary Sjögren's syndrome, a fivefold increased risk for lymphoma is conferred by the presence of parotid gland enlargement, splenomegaly, lymphadenopathy, neutropenia, cryoglobulinemia, or low C4.¹²⁹

Associated Diseases

Primary Sjögren's syndrome has been associated with a higher risk for the development of other autoimmune diseases including thyroid disease, autoimmune hepatitis, primary biliary cirrhosis, and celiac disease. Although initial studies found a higher frequency of thyroid disease in patients with primary Sjögren's syndrome than controls, a recent, larger study failed to show a statistically significant difference in the rate of thyroid disease between the two groups.¹³⁰ Autoimmune hepatitis and primary biliary cirrhosis occur in less than 5% of patients with primary Sjögren's syndrome, but more precise estimates of their prevalence are not available owing to the absence of well-controlled studies addressing this question. One exception is a Hungarian study showing a 10-fold higher rate of celiac disease in patients with primary Sjögren's syndrome compared with healthy controls.¹³¹

DIAGNOSIS AND DIAGNOSTIC TESTS

Keratoconjunctivitis Sicca and Xerostomia

A diagnostic suspicion of Sjögren's syndrome is initially raised by complaints of dry eyes and dry mouth. However, many patients do not openly volunteer this information because they do not feel it is important enough to bring to the attention of the physician. Therefore it is essential to inquire about these symptoms if they do not come up during initial history taking. In patients with symptoms of dry eyes and dry mouth, the next step is to confirm the diagnosis by objective testing. An easy method for evaluating aqueous tear flow is the Schirmer's-I test, which is performed by inserting a sterile piece of filter paper in the middle to lateral third of the lower eyelid and measuring the distance tears elute over 5 minutes. A distance of 5 mm or less is the usual cutoff for abnormally low tear production. Although a Schirmer-I test is subject to an approximately 20% rate of false negativity, normal tear flow in the face of ocular foreign body sensations suggests an alternative diagnosis such as blepharitis (see later). Patients with moderate-to-severe symptoms of dry eyes are usually referred to an ophthalmologist for slit-lamp examination. With a slit-lamp, the ophthalmologist can carefully examine the ocular surface, evaluating for any signs of damage. Instillation of lissamine green or fluorescein dye onto the surface of the eye displays the integrity of the conjunctival and corneal surface. Lissamine green dye stains epithelial surfaces lacking mucin (Figure 73-4), whereas the fluorescein dye targets areas of cellular disruption on the ocular surface. Rose Bengal dye, which stains dead or degenerated cells, is no longer preferred for evaluating the ocular surface due to its toxic effects on the cornea.

Several methods may be used for objective assessment of dry mouth, or xerostomia. Only a minority of patients with xerostomia show obvious signs of a dry mucosa on oral examination (e.g., absent sublingual salivary pool, thick and sticky saliva). Sialometry is used to test for functional impairment in salivary flow and refers to the measurement of salivary flow from individual glands (parotid, submandibular, or sublingual) or the mouth as a whole. An unstimulated whole salivary flow rate less than or equal to 1.5 mL/15 min meets the criterion for xerostomia according to the classification criteria developed by the American-European Consensus Group (see Table 73-1). For the collection procedure, the patients should keep their heads tilted forward and swallow once to clear the mouth of excess saliva. At this point, the 15-minute collection period is initiated and then subjects expectorate, as needed, accumulating saliva into a preweighed 50-cm³ cryovial. Samples are weighed on an analytic balance to determine the volume (1 g = 1 mL) of saliva.

Sialography, another technique for evaluating xerostomia, visualizes radiographic patterns of duct obstruction in the major salivary glands. It is most useful for differentiating an inflammatory process from a neoplasm. This technique calls for injection of radiographic contrast dye into the salivary duct followed by serial radiographs to image the pattern of dye flow. A water-based contrast is strongly preferred to an oil-based contrast because the latter may damage the adjacent salivary gland tissue. Sialography is not routinely

Figure 73-4 Lissamine staining of a dry eye as shown by slit-lamp examination. **A**, Punctate staining of the cornea. **B**, Punctate staining of the conjunctival epithelium. (**A** and **B**, Courtesy W. Craig Fowler, MD, Department of Ophthalmology, University of North Carolina at Chapel Hill.)

employed in clinical practice because it is an invasive procedure with complications including duct rupture, pain, and infection. Scintigraphy is a radionuclide technique for measuring salivary gland function. After sodium radiolabeled pertechnetate technetium is injected into the blood, it is absorbed into the salivary gland and secreted into the mouth, allowing for determination of the salivary flow rate. The diagnostic sensitivity and specificity of salivary gland scintigraphy for the diagnosis of primary Sjögren's syndrome has been estimated to be 75% and 78%, respectively.¹³² Salivary scintigraphy is not widely available for routine testing.

Ultrasonography and MRI have been examined for their ability to detect anatomic abnormalities in the salivary glands of patients with primary Sjögren's syndrome. In comparison with normal individuals, the detection of parenchymal inhomogeneity by ultrasonography in two or more major salivary gland had a sensitivity of 63% and a specificity of 99% for identifying patients with primary Sjögren's syndrome.¹³³ Although these results are promising, this technique requires further validation and investigation using appropriate disease controls. MRI with sialography may be more sensitive than ultrasonography for detecting glandular structural changes,¹³⁴ but further studies are necessary to validate this technique as well.

Labial Salivary Gland Biopsy

Labial salivary gland biopsy has long been considered the gold standard for diagnosing primary Sjögren's syndrome. However, in clinical practice, its use is often reserved for patients in whom the diagnosis remains unclear after a thorough clinical and laboratory evaluation. The biopsy is usually performed by an oral surgeon or otolaryngologist, or other appropriately trained individual. This minor procedure calls for removal of four or more salivary gland lobules through a small incision in the inner lip. A biopsy is considered to be positive if histopathologic analysis shows a focus score of greater than or equal to 1 per 4 mm² of tissue, where a focus is defined as a cluster of 50 or more lymphocytes. Using a focus score of greater than or equal to 1 as the cutoff, the sensitivity and specificity of labial salivary gland biopsy for the diagnosis of primary Sjögren's syndrome was reported to be 83.5% and 81.8%, respectively.^{19,20} The interpretation of labial salivary gland biopsies is subject to considerable inter-reader variability depending on the experience of the reader. Therefore it is recommended that the biopsy slides be read by an experienced pathologist or other specialist with an appreciation for the nuances of interpretation.

Laboratory Evaluation

Most patients with primary Sjögren's syndrome test positive for serum ANAs. In a large study from Spain, ANAs were detected in sera from 85% of patients with primary Sjögren's syndrome.¹³⁵ Approximately one-half and one-third of patients with primary Sjögren's syndrome in this study had anti-Ro/SS-A and anti-La/SS-B antibodies, while about 50% of patients tested positive for rheumatoid factor. There also appears to be a small subset of patients (<5%) with primary Sjögren's syndrome that test negative for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies, but positive for serum anti-centromere antibodies. In one study, such patients with serum anticentromere antibodies had a lower prevalence of dry eyes, hypergammaglobulinemia, and anti-Ro/SS-A and anti-La/SS-B antibodies than other patients with primary Sjögren's syndrome, as well as a higher prevalence of Raynaud's syndrome.¹³⁶

About 5% to 10% of patients with primary Sjögren's syndrome have low blood levels of C3 and C4. For example, 9% of the Spanish cohort referred to earlier had low C3 or C4 levels (13%). About the same proportion of patients with primary Sjögren's syndrome has either type II or III cryoglobulinemia or a monoclonal gammopathy.¹³⁵ In type II cryoglobulinemia, the monoclonal gammopathy is usually an IgMκ that has rheumatoid factor activity when the patient resides in a Western or European country; patients of Japanese descent express a higher prevalence of IgA and IgG monoclonal gammopathies.¹³⁷ Hematologic abnormalities are observed in about 5% to 15% of patients with primary Sjögren's syndrome and include leukopenia and thrombocytopenia.

Approach to Diagnosis

The clinical diagnosis of primary Sjögren's syndrome is highly likely if a patient with symptoms of dry eyes and dry

mouth has objective evidence of keratoconjunctivitis sicca and/or xerostomia in conjunction with a positive test for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies. It may not be necessary to obtain objective evidence of salivary gland involvement if the other clinical and laboratory features are consistent with this diagnosis. In some cases, a clinical diagnosis of primary Sjögren's syndrome may be made in the absence of serum anti-Ro/SS-A and/or anti-La/SS-B antibodies but a moderately or strongly positive test for ANAs. Although accepting a positive ANA alone as the serologic criterion lowers diagnostic specificity, the other clinical and laboratory features can be taken into consideration when making a diagnosis of primary Sjögren's syndrome as opposed to another connective tissue disease or related condition. Because approximately 25% to 50% of patients with primary Sjögren's syndrome test negative for anti-Ro/SS-A and anti-La/SS-B antibodies, a positive test for ANAs may often be the only evidence of an immune-mediated process. Serum ANAs of low titer have relatively little diagnostic value in this setting.

Biopsy of the labial salivary glands may be warranted in cases where signs and symptoms of keratoconjunctivitis sicca and xerostomia are not accompanied by convincing serologic evidence of autoimmunity. The labial salivary gland biopsy is used in this scenario to confirm that glandular hypofunction is associated with a chronic inflammatory process and to explore alternative diagnoses such as sarcoidosis or amyloidosis. In most of these situations, relatively few labial salivary gland biopsies will prove to be positive (focus score ≥ 1), although a negative result probably reduces the likelihood of primary Sjögren's syndrome to less than 5%.

The diagnosis of primary Sjögren's syndrome in children and adolescents may require special consideration. Compared with adults, children and adolescents present more often with recurrent parotitis, which is not included as a criterion in the recent classification schemes. It has been shown that the inclusion of recurrent parotitis in the classification criteria validated by the American-European Consensus Group increases the sensitivity of diagnosing primary Sjögren's syndrome in children and adolescents from 39% to 76%.³⁰

Differential Diagnosis

The differential diagnosis of primary Sjögren's syndrome is broad owing to the variety of conditions that also cause dry eyes and mouth, salivary gland enlargement, and a similar profile of extraglandular manifestations (see [Table 73-3](#)). It is important to realize that most patients diagnosed with keratoconjunctivitis sicca by an ophthalmologist do not have primary Sjögren's syndrome, despite a deficiency in aqueous tear flow. The etiology of keratoconjunctivitis in these cases is often obscure and presumably related to aging or hormonal changes or other degenerative processes. Evaporative tear loss secondary to meibomian gland dysfunction is another common cause of dry eyes. Many anticholinergic medications are contributing factors to the sicca complaints. Because approximately 25% of the general population has symptoms of dry mouth, it is not surprising that dry eyes and dry mouth often may coexist in the same patient in the absence of a systemic disease such as Sjögren's syndrome.

Chronic parotitis in association with the sicca complex strongly suggests the diagnosis of Sjögren's syndrome or possibly another systemic disease. Sarcoidosis often comes up in the differential diagnosis of primary Sjögren's syndrome and may even coexist with it. Bilateral diffuse enlargement of the parotid glands from sialadenosis, a noninflammatory process, also may occur in patients with diabetes mellitus who suffer from dry eyes and mouth. In addition, severe hypertriglyceridemia, chronic liver disease, and alcoholism have been associated with sialadenosis and enlargement of the major salivary glands.

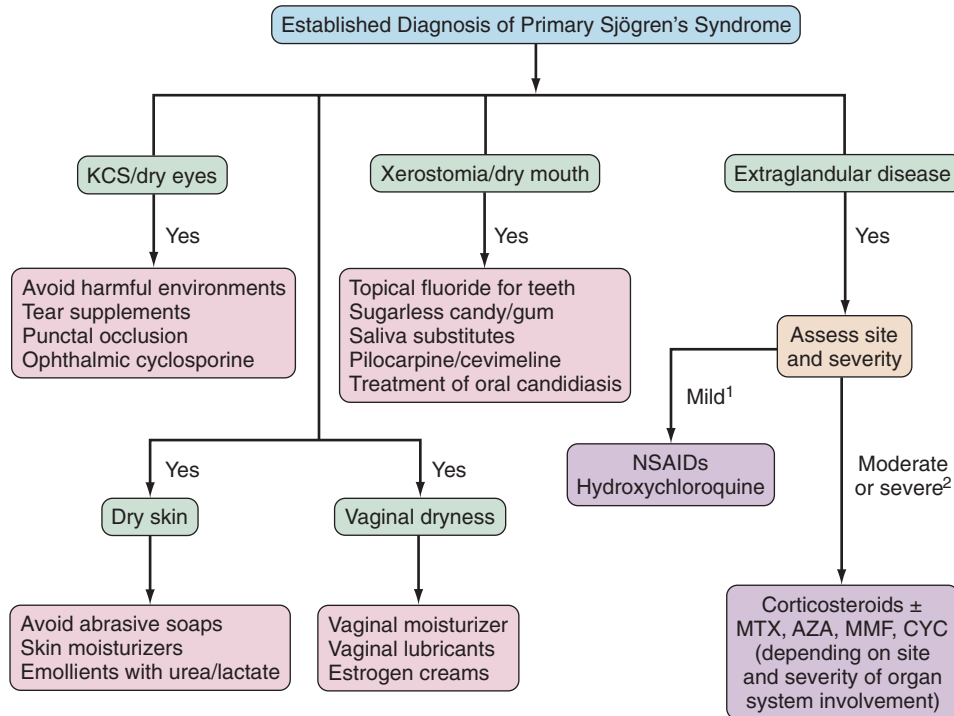

A relatively new clinical entity, termed *IgG4-related syndrome* or *IgG4 positive multiorgan lymphoproliferative syndrome*, is emerging as an important consideration in the differential diagnosis of primary Sjögren's syndrome. IgG4-related syndromes are uniquely characterized by high serum levels of IgG4 and tissue biopsies showing a marked infiltration of IgG4⁺ plasma cells coupled with fibrosis or sclerosis. Compared with primary Sjögren's syndrome, IgG4⁺-related syndromes do not show the same female predominance and are associated with a lower frequency of dry eyes and mouth, arthralgia, and serum ANA positivity, as well as a higher rate of autoimmune pancreatitis.¹³⁸

TREATMENT

The treatment of primary Sjögren's syndrome aims at reducing the signs and symptoms of dry eyes and dry mouth and ameliorating systemic manifestations ([Figure 73-5](#)). Sicca complaints may be lessened in general by withdrawal of medications with drying effects. For the treatment of dry eyes, the patient is advised to avoid central heating and air conditioning, windy environments, and medications that reduce tear and saliva production. Tear supplements are available over the counter in various formulations of different viscosities. Low-viscosity tears are administered more often than high-viscosity tear formulations, which are most useful at bedtime for prolonged lubrication during the sleeping hours. Artificial tears are also available with and without preservatives. Preservative-based tears may worsen dry eyes if they are instilled more than four times per day owing to their toxic effects on the ocular surface. More frequent instillation of tears warrants use of formulations without preservatives.¹³⁹

An ophthalmic preparation of cyclosporine 0.05% (Restasis) has been approved by the U.S. Food and Drug Administration for the treatment of keratoconjunctivitis sicca. In clinical trials, ophthalmic cyclosporine 0.05% has been shown to reduce the signs and symptoms of dry eyes including a statistically significant improvement in tear flow as measured by the Schirmer-I test. Many patients have trouble tolerating ophthalmic cyclosporine because of its burning effects.

Tears may be conserved by blocking the nasolacrimal drainage channels with temporary or permanent occlusion of the punctae, a relatively simple procedure performed by an ophthalmologist. This procedure may be performed in patients with persistent symptoms of dry eyes despite use of artificial tears. Plugs are initially placed in the two inferior punctae because 90% of the tears drain through these channels. Plugs may be later employed to block the two superior

²NSIP or LIP, interstitial nephritis, PNS involvement with motor weakness, systemic necrotizing vasculitis, CNS involvement with focal deficits or severe cognitive dysfunction

Figure 73-5 Treatment algorithm for Sjögren's syndrome. The treatment of Sjögren's syndrome usually requires a multidisciplinary approach involving rheumatologists, ophthalmologists, dentists/oral surgeons, otolaryngologists, and other subspecialists depending on the extent of extraglandular disease. In all cases, it is prudent to minimize the use of medications that can exacerbate the symptoms of dryness such as antihistamines, antidepressants, muscle relaxers, and other drugs with anticholinergic properties. The treatment of extraglandular disease is individualized according to the site and severity of organ system involvement. The approaches indicated in the algorithm for the treatment of extraglandular disease are not supported by evidence from randomized, controlled trials, but rather from expert opinion based on retrospective case series and clinical experience. AZA, azathioprine; CNS, central nervous system; CYC, cyclophosphamide; KCS, keratoconjunctivitis sicca; LIP, lymphocytic interstitial pneumonitis; MMF, mycophenolate mofetil; MTX, methotrexate; NSAIDs, nonsteroidal anti-inflammatory drugs; NSIP, nonspecific interstitial pneumonitis; PNS, peripheral nervous system.

punctae. Excessive tearing is the most frequent complication of punctal occlusion, which is the rationale for a trial of temporary blockade with dissolvable collagen plugs. Long-term blockage may be achieved using silicone plugs or surgery by cauterization or a laser.

Blepharitis, which commonly occurs in patients with dry eyes, often complicates a dry eye state. Patients with blepharitis may benefit from warm compresses and lid scrubs using an eyelid detergent such as Johnson's Baby Shampoo mixed 1:1 with water. More refractory cases of blepharitis may be managed with chronic doxycycline therapy. Occasionally, the tear film may contain excessive mucous debris that can be dispersed by instillation of a 10% acetylcysteine ophthalmic solution, a mucolytic agent that can be compounded by a pharmacy.

A dry mouth may be managed by replacing existing saliva or stimulating residual salivary flow. Various over-the-counter preparations of artificial saliva are available containing hypromellose or methylcellulose. However, they provide limited relief in most cases because of their short duration of action. Patients may stimulate salivary flow by sucking on sugarless candy or chewing sugarless gum. Two

oral secretagogues are available by prescription that stimulate saliva and tear flow. Pilocarpine (Salagen), which acts by stimulating the M3R, is given at a dose of 5 mg three to four times daily and has been shown in controlled clinical trials to improve subjective and objective measures of both dry eyes and dry mouth.^{140,141} Cevimeline (Evoxac) also stimulates the M3R and has been similarly shown in trials to improve subjective and objective measures of dry eyes and mouth.¹⁴² Common side effects of these two secretagogues are sweating and flushing, which derive from their mechanism of action. Other possible side effects include visual disturbances, increased urination, nausea, abdominal pain, and diarrhea. Due to their pharmacologic properties, pilocarpine and cevimeline are contraindicated in patients with iritis, narrow angle glaucoma, and moderate-to-severe asthma.

Because xerostomia predisposes to dental carries and broken teeth, daily flossing, frequent dental visits, and regular fluoride applications are recommended for prevention purposes. Oral candidiasis, another complication of xerostomia, may be treated for 10 to 14 days with a nystatin elixir, clotrimazole troches, or fluconazole. Clotrim-

azole cream is beneficial for the treatment of angular cheilitis, which typically accompanies oral candidiasis.

Patients with primary Sjögren's syndrome also suffer from dryness of the lips, skin, and nasal passages. This problem may be addressed by the frequent application of moisturizers, lip balm, and nasal saline spray. The oily content of vitamin E softgel capsules may be used topically on the skin or the lips for its moisturizing effects. Vaginal dryness with dyspareunia is a frequent complaint of women with primary Sjögren's syndrome. This condition may respond to moisturizers and treatment with a topical estrogen cream. Vaginal lubricants may be necessary for treatment of dyspareunia.

Currently, the therapeutic armamentarium of primary Sjögren's syndrome lacks a proven disease-modifying drug. Clinical experience suggests that symptoms of fatigue, myalgia, and arthralgia/arthritis may respond favorably to treatment with hydroxychloroquine; however, the efficacy of this approach has not been proven in a randomized, controlled clinical trial. Care is taken to avoid doses of hydroxychloroquine exceeding 6.5 mg/kg/day to minimize the risk of retinal toxicity. When this drug is used long term, annual ophthalmologic examinations are recommended to monitor for possible retinal toxicity.

Corticosteroids and other immunosuppressive drugs are often employed for the treatment of organ-threatening extraglandular disease. NSIP and LIP are usually treated with high doses of corticosteroids and other immunosuppressive agents such as azathioprine, mycophenolate mofetil, or cyclophosphamide. Because virtually no controlled data are available supporting the use of these agents for NSIP or LIP, this approach is necessarily empiric and demands judicious monitoring and close follow-up. Bronchiolitis typically improves with high doses of corticosteroids alone, but close follow-up is mandatory for treatment of relapses. Patients who are asymptomatic and have had PFTs showing an isolated mild reduction in DLCO or evidence of small airway disease may be carefully followed without treatment.

Conservative measures may be the only therapy for a sensory peripheral neuropathy where medications such as gabapentin and analgesics may help to control the aggravating and painful neuropathic symptoms. High doses of corticosteroids may produce transient improvement in the symptoms of a peripheral neuropathy, but it is unclear if they provide any long-term benefits and if the benefits outweigh the risks of this treatment. Clinically demonstrable motor loss calls for a more aggressive treatment approach using corticosteroids and other immunosuppressive agents. Some patients with severe motor involvement may benefit from treatment with intravenous immunoglobulin.

A minority of patients with primary Sjögren's syndrome develop recurrent lower extremity purpura. These lesions usually cause burning and stinging and may be associated with lower extremity edema, but they rarely ulcerate. Although moderate to high doses of corticosteroids afford symptomatic relief in most cases, subsequent tapering to low doses and withdrawal usually leads to recurrence of the purpura. Corticosteroid therapy may be avoided in the absence of severe and uncontrollable symptoms or progression to skin ulceration. Support stockings provide symptomatic relief in many cases and can be used in combination

with analgesics, antihistamines, or nonsteroidal anti-inflammatory drugs to manage the painful symptoms. The patients are usually left with postinflammatory changes in the skin, which may be an acceptable outcome given the long-term side effects of corticosteroids.

Biologic therapies have been investigated recently for their clinical efficacy and safety in primary Sjögren's syndrome. Infliximab and etanercept, which are TNF inhibitors, have failed in controlled clinical trials to demonstrate therapeutic benefit.^{143,144} Preliminary studies of rituximab and epratuzumab have produced mixed results so far,¹⁴⁵⁻¹⁴⁸ and larger studies will be necessary to provide more convincing evidence of clinical efficacy and safety for this indication. Other biologics are on the horizon and will likely be investigated for the treatment of primary Sjögren's syndrome in the near future. The interest in finding a disease-modifying therapy for primary Sjögren's syndrome has led to the initial development of disease activity and damage measures,^{149,150} which will require subsequent validation in clinical trials.

OUTCOME

Overall mortality is not increased in patients with primary Sjögren's syndrome compared with the general population, although the subgroup of patients with extraglandular disease has an increased risk of morbidity and death. Compared with the general population, Ioannidis and colleagues¹⁵¹ showed that mortality was not significantly higher in a cohort of 723 patients with primary Sjögren's syndrome. In this study the patients were subdivided into types I and II according to their risk for complications and death. Approximately 20% of the patients fell into the high-risk, type I group, whereas the remainder in the type II group had no increase in the risk for complications or death. In the type I group, patients presenting with palpable purpura and low C4 levels had a higher risk for long-term complications and death.¹⁵¹ Similar results were found in another study showing no increase in all-cause mortality among individuals with primary Sjögren's syndrome.¹⁵² Hypocomplementemia has been confirmed as a risk factor for adverse outcomes in another cohort of 336 patients with primary Sjögren's syndrome from Spain.¹⁵³

The disease mechanisms of primary Sjögren's syndrome are being probed with increased interest. The labial salivary gland tissue is readily accessible for biopsy, and the new technologies are dramatically accelerating understanding of the complex pathways intertwining the aberrant innate and adaptive immune responses in this disease. Genetics and genomics are only beginning to permeate the scientific investigation of primary Sjögren's syndrome, and predictably this gap will be filled in the near future. An unanswered question of major import is the cause of the glandular hypofunction. In the earlier stages of disease, it appears that glandular damage does not adequately explain the impaired salivary flow, suggesting that autoantibodies, the cytokine milieu, or both, or other mediators are contributing to these functional abnormalities. Further studies are necessary to address this question owing to the potential reversibility of glandular dysfunction and the nature and timing of therapeutic interventions to be tested in the future.

Although primary Sjögren's syndrome cannot yet claim a disease-modifying therapy, much can be done for patients with this disease by effectively managing the sicca component, ameliorating fatigue and joint pain with hydroxychloroquine therapy, and monitoring for complications. Although biologics such as rituximab may yet prove to be useful for treating Sjögren's syndrome, new therapeutic targets illuminated by translational research will shape the discovery of disease-modifying therapies down the road. Proof of therapeutic efficacy will require instruments that quantify disease activity and damage that are only now under development. Finding that first drug with the properties of disease modification will go a long way toward moving the field forward and expanding the therapeutic options for patients with primary Sjögren's syndrome in the decades to come.

CONCLUSIONS

Primary Sjögren's syndrome occurs nearly as often as rheumatoid arthritis and greater than 10 times more frequently than systemic lupus erythematosus. Therefore it ranks second in prevalence only to rheumatoid arthritis among the autoimmune disorders in the domain of rheumatology. Many patients with mild forms of primary Sjögren's syndrome probably never come to the attention of the rheumatologist, but rather are managed exclusively by primary care physicians, ophthalmologists, otolaryngologists, and dentists. Others may never be referred for a diagnosis because of the frequent misperception that little can be done for patients with Sjögren's syndrome. However, primary Sjögren's syndrome is a systemic autoimmune disease associated with lung, neurologic, and renal involvement; vasculitis; and an increased risk for a low-grade B cell lymphoma, and the rheumatologist is aptly trained to provide an accurate diagnosis and deal effectively with the multisystem complications of this disease.

Pathogenesis of Ankylosing Spondylitis and Reactive Arthritis

DAVID YU • RIK LORIES •
ROBERT D. INMAN

KEY POINTS

Genetics plays a major role in the etiology of ankylosing spondylitis.

The gene with the greatest contribution to ankylosing spondylitis is HLA-B27.

A major mediator of inflammation is tumor necrosis factor (TNF).

Bone destruction occurs along with pathologic new bone formation in ankylosing spondylitis.

The bone remodeling processes are not necessarily directly linked to the inflammatory processes in ankylosing spondylitis.

Reactive arthritis is initiated by infection outside the joints.

At least in the case of *Chlamydia*-induced arthritis, a modified form of the pathogen can be detected in the joints of some patients.

Ankylosing spondylitis and reactive belong to the family of spondyloarthritis. Reactive arthritis (ReA), is clearly distinct in that it is induced by an episode of acute infection. Accordingly, the pathogenesis of these two diseases will be described in separate sections. For ankylosing spondylitis, it is commonly recognized that two major but “uncoupled” processes coexist inflammation and abnormal bone formation.¹ The process of bone formation in this disease has become a major research frontier.

PATHOGENESIS OF ANKYLOSING SPONDYLITIS

The causes of ankylosing spondylitis are multifactorial and involves a number of interlinking pathways. A considerable number of critical factors have been identified. They can be classified into two groups. One group consists of mediators that are midstream in the pathways leading to inflammation. These mediators are targets of current therapies. The second group of critical factors contributing to ankylosing spondylitis is genetics. How should the degree of contribution of each factor be estimated? For therapeutics, the

usefulness of each therapy will be ranked by a statistical value known as *effect size*. In pharmacology, effect size reflects the size of the difference in outcome between groups receiving a drug compared with a group receiving placebo, taking into account the degree of variability within groups. The higher the effect size, the more effective is the therapy. For ranking the genes, we will use the statistical value known as the *population attributable risk*. For each gene, this value represents the incidence of disease in a population that would be eliminated if the gene is absent. The higher the population attributable risk, the greater the contribution to the disease.²

Causes of Ankylosing Spondylitis That Are Targets of Therapies

It has been known for more than three decades that most patients with ankylosing spondylitis demonstrate a highly satisfactory response to treatment with nonsteroidal anti-inflammatory drugs (NSAIDs), including the cyclooxygenase-2 (COX-2) inhibitors (coxibs).³ The effect size for spinal pain is 1.11, which means that there is a 77% probability that a randomly selected NSAID-treated patient will show a better response than a randomly selected placebo-treated patient.⁴ This effect size is much greater than in patients with nonspecific chronic low back pain.⁵ Because the molecular targets of most NSAIDs are COX-1 and COX-2, and the target of the coxibs is restricted to COX-2, it can be concluded that one of the pathways causing spinal pain in ankylosing spondylitis is the COX-2 pathway.⁶ Indeed, the COX-2 pathway generates prostaglandins and thromboxanes, which are strongly proinflammatory. The response of spinal pain in ankylosing spondylitis to NSAIDs is indirect evidence that inflammation is responsible for the pain. In fact, the spinal pain of ankylosing spondylitis is designated as being “inflammatory” rather than “mechanical.” The presence of spinal inflammation is validated by magnetic resonance imaging (MRI) observations.⁷ Although we know that the COX-2 pathway is responsible in part for the symptoms of ankylosing spondylitis, no information is available as to what triggers

this pathway or which downstream mediators are most important.

When responses to NSAIDs are not satisfactory, some patients will be given a trial of a disease-modifying antirheumatic drug (DMARD). Most of the conventional DMARDs useful for rheumatoid arthritis such as methotrexate are much less effective in ankylosing spondylitis.⁴ Similar to rheumatoid arthritis, for patients who are resistant to treatment with NSAIDs or conventional DMARDs, there is a very high rate of clinical response to biologically generated agents that target tumor necrosis factor (TNF). Currently, several of these biologics have been approved for the treatment of ankylosing spondylitis in the United States. All are very effective in controlling symptoms. The effect size for etanercept, for example, is 2.25, which means that more than 90% of randomly selected patients will respond better than another randomly selected patient who is treated with placebo.⁴ Hence there is little doubt that TNF is a major player in causing the symptoms of ankylosing spondylitis. TNF is a cytokine generated via innate and adaptive immunities by several types of cells, including macrophages, T lymphocytes, and mast cells. TNF is not a factor with a single pathway inducing a single event in a single type of cell. Rather, it is pleiotropic in affecting many cell types, and it induces a network of cytokines and chemokines and other mediators of inflammation.⁸ Although it is certain that TNF is a major early upstream mediator in ankylosing spondylitis, no agreement has been reached as to which cell types are specifically responsible for generating TNF, or which processes are disease-specific targets of TNF.

Information derived from the most effective modalities of treatment currently available for ankylosing spondylitis does not provide any concrete clues regarding fundamental causes. As with most chronic diseases, the fundamental causes must be a combination of environmental and genetic factors. What we first need to estimate in ankylosing spondylitis is the degree of contribution of environmental versus genetic factors.

ASSESSMENT OF DEGREE OF CONTRIBUTION BY ENVIRONMENTAL VERSUS GENETIC FACTORS AND IDENTIFICATION OF GENETIC FACTORS

Degrees of contribution of environmental versus genetic factors have been estimated from the degree of concordance among twins. According to those analyses, genetics contributes to more than 90% of the total cause of ankylosing spondylitis. In addition, if there are environmental causes, they are probably ubiquitous, such as enteric bacteria.⁹ Indeed, rats carrying the human ankylosing spondylitis-causing transgene HLA-B27 do not develop arthritis when bred in a germ-free environment. However, arthritis will develop once they are transferred to a regular environment.¹⁰ It is thought that the development of arthritis in these rats is related to commensal bacteria, especially in the gastrointestinal tract. In human ankylosing spondylitis, the only enteric bacterium that has been incriminated is *Klebsiella pneumoniae*. As a group, patients with ankylosing spondylitis have higher mean antibody titers to *Klebsiella* compared with control subjects.¹¹ However, evidence

supporting *Klebsiella* as a cause of ankylosing spondylitis is far less strong than that which supports, for example, that streptococcal infections are a cause of rheumatic fever.

Over the past decade, most of the researchers studying the pathogenesis of ankylosing spondylitis have focused on identification of arthritis-causing genes. According to statistical modeling based on family studies, the disease is caused by up to nine genes with multiplicative interactions among loci.¹² The most important gene, HLA-B27, was discovered in 1973.^{13,14} It contributes about 30% of the heritability of the disease. About three decades later, with the development of the technique of genome-wide association study of nonsynonymous single-nucleotide polymorphisms (SNPs), at least four other loci encoding known structural gene sequences have now been reported. In the Wellcome Trust Case Control Consortium and the Australo-Anglo-American Spondylitis Consortium studies, when these genes are ranked according to their degree of contribution, they are listed as follows: HLA-B27, ERAP1 (endoplasmic reticulum amino peptidase 1, previously known as aminopeptidase-regulating tumor necrosis factor receptor shedding 1, abbreviated as ARTS-1), IL-23R (interleukin 23 receptor), IL-1R2 (interleukin 1 receptor, type II), and ANTXR2 (anthrax toxin receptor, also known as capillary morphogenesis protein 2, or CMG2). The population attributable risks for the first three are 90%, 26%, and 9%, respectively. Those for IL-1R2 and ANTXR2 are probably less than 5%.^{15,16} Hence, HLA-B27 is the largest contributor.

How HLA-B27 Induces Ankylosing Spondylitis

The most important gene in ankylosing spondylitis is HLA-B27. In most populations, it is present in more than 90% of patients and in less than 10% of the general population.¹⁷ Rats carrying the HLA-B27 transgene develop arthritis and colitis.^{18,19} Using gene terminology from microbiology, it is described as being “essential” for ankylosing spondylitis. Because the association between HLA-B27 and ankylosing spondylitis has been known for more than three decades, the search for how HLA-B27 causes ankylosing spondylitis has been the Holy Grail of many scientists, and an enormous number of publications have been generated. HLA-B27 is an allele of the HLA-B locus of the human leukocyte antigen (HLA) class I antigens. Multiple subtypes of HLA-B27 have been defined.²⁰ Most experiments attempting to identify the mechanisms of how HLA-B27 mediates arthritis have been carried out with the more common B27*05 and B27*04 subtypes. Multiple hypotheses have been reported regarding how HLA-B27 molecules mediate arthritis. At least three hypotheses are currently under active investigation.

Arthritogenic Peptide Hypothesis

The arthritogenic peptide hypothesis is based on the classic structure and the canonical function of HLA-B alleles. As in all HLA class I molecules, a classic HLA-B27 molecule is a trimolecular complex of a polymorphic HLA class I heavy chain together with a monomorphic light chain (β2-microglobulin [β2m]) and a single highly variable peptide (Figure 74-1). Most of the peptides are nanomers that

Figure 74-1 Three different structures of HLA-B27 and how they might induce the processes of arthritis. HLA-B27 is first generated as a free heavy chain, which inside the cell becomes associated and folded with β 2-microglobulin (β 2m) and antigenic peptide, and then becomes expressed on the cell surface as a trimolecular complex. It can also be expressed on the cell surface as homodimers of heavy chains without β 2m. ER, endoplasmic reticulum; KIR, killer-cell immunoglobulin-like receptor; LILR, leukocyte immunoglobulin-like receptor; NK, natural killer.

conform to a strict motif, usually with arginine as the second amino acid. The motif of peptides that bind to HLA-B27 is different from that of peptides that bind to other HLA-B alleles or to HLA-A or -C molecules.^{21,22} These polymorphisms probably are driven by evolution to survey against ever changing pathogens such as the influenza viruses. The canonical function of HLA-A and -B molecules is to present peptides derived from such intracellular pathogens to CD8⁺ T lymphocytes to generate a protective adaptive immune response.²³ The reason why this is vulnerable to autoimmunity is that most of the peptides complexed with HLA-A and -B molecules are derived from self-proteins. In health, the hosts are tolerant to all these self-peptides.

The arthritogenic peptide hypothesis postulates that in the case of ankylosing spondylitis, there is a breakdown of tolerance to certain self-peptides, and this breakdown is a consequence of mimicry between the self-peptides and certain pathogen-derived and arthritis-causing peptides.²⁴ Identification of these arthritogenic peptides demands a great deal of fundamental information concerning the quaternary structures of the HLA-peptide complexes, as well as the dynamics of these structures, the peptide repertoires of candidate pathogens, the repertoires of self-peptides, and last, the repertoires of T cell receptors. At this

point, enormous detail has been generated concerning the structures of HLA-peptide complexes. Reactivity against several self-peptides has also been reported. Many yet untested candidate peptides have recently been identified and will require testing in the future, perhaps with newly developed immunoproteomic techniques.^{25,26}

Free Heavy Chain Hypothesis

The free heavy chain hypothesis is based on the observation that HLA-B27 molecules can exist on the cell surface as free heavy chains free of the more usual association with β 2m or peptides with the classic HLA-B27 motif (see Figure 74-1). These free heavy chains exist as stable dimers and are capable of engaging allele-specific receptors on natural killer (NK) cells and T lymphocytes. Receptors for HLA-B27 free heavy chain dimers are the *KIR3DL1*001* allele of KIRs (a family of immunoglobulin-like receptors on NK cells and certain subsets of T cells) and the *LILRA1* and *LILRB2* alleles of LILRs (a family of leukocyte immunoglobulin-like receptors on NK cells, T and B cells, and cells of the myeloid lineage).²⁷ The free heavy chain hypothesis postulates that engagement of these receptors will generate arthritis-causing events. This hypothesis is supported by actual observations of ankylosing spondylitis patients. Such HLA-B27 heavy chain dimers are found on the cell surfaces of mononuclear cells, along with expansion of KIR3DL2-expressing NK and CD4⁺ T cells responding to such dimers.^{28,29}

Unfolded Protein Hypothesis

The unfolded protein hypothesis is different from the previous two in that it is concerned not with activities of HLA-B27 on the cell surface, but with activities inside the cells (see Figure 74-1). Like most surface proteins, the HLA-B27 heavy chains are synthesized linearly into a processing organelle inside the cell by the endoplasmic reticulum (ER). At first, these newly synthesized proteins do not have any conformation and are described as being “unfolded.” Then, they are stepwise driven into a series of conformations through sequential complexing with a corresponding series of ER chaperones. These ER chaperones generate conformations in their target proteins by binding to their inappropriately exposed hydrophobic domains, as well as to underglycosylated residues. Through a series of cycles of binding and release with a series of ER chaperones, formation of disulfide bonds, and pairing with the β 2m and a peptide, an HLA-B27 molecule will mature into a quaternary and stable form, which then will be transported to the cell surface.³⁰

This sequence of events takes place over a period of time. Compared with a few other common HLA alleles, HLA-B27 heavy chains have more prolonged retention times inside the ER. In addition, with HLA-B27, more partially misfolded and unfolded forms are found inside the ER compared with other HLA alleles. Reasons include aberrant disulfide bond formation and multimer formation among the heavy chains, among others. These partially folded or misfolded HLA-B27 proteins remain for a time sequestered inside the ER, being complexed with chaperones such as the “immunoglobulin heavy chain-binding protein,”

abbreviated as BiP (GRP78, 78-kD glucose-regulated protein). BiP is a sensor for accumulation of misfolded proteins. It initiates several ER processes, which together are termed *unfolded protein response* (UPR).^{31,32} UPR can be cytoprotective or might lead to apoptosis. UPR is associated with a number of diseases, including cancer, diabetes, atherosclerosis, and neurologic disorders. For ankylosing spondylitis, it has been observed in an in vitro system that UPR with HLA-B27 polarizes the cells in response to lipopolysaccharide to cross-talk with the cytokine systems by generating interleukin (IL)-23. The HLA-B27 unfolded protein hypothesis postulates that HLA-B27 induces an unfolded protein response, which, in conjunction with activation by pattern recognition receptors (PRRs) such as those for lipopolysaccharide, would generate proinflammatory cytokines to such a degree as to cause arthritis.^{32,33}

How Non-Major Histocompatibility Complex Genes Modify HLA-B27 Physiology

Each of the three hypotheses of how HLA-B27 causes ankylosing spondylitis are based to a large extent on in vitro observations, to a lesser extent on observations in animal models, and even less on patient-derived samples. They are working hypotheses in the sense that they are not yet capable of being translated to the bedside for diagnosis or for development of therapeutics. However, strong support has appeared recently from studies of the biology of ankylosing spondylitis-associated genes identified by the genome-wide association study.

Probably the most important non-major histocompatibility complex (MHC) gene discovered so far is *ERAP1*. The association of *ERAP1* with ankylosing spondylitis has been replicated in multiple populations, including white and nonwhite ethnicities.³⁴ Equally significant, in one familial study, disease association has been extended to a haplotype of *ERAP1* and *ERAP2*, indicating that the disease association is with a biology common to *ERAP1* and *ERAP2*.³⁵ *ERAP1* and *ERAP2* are metalloproteinases sharing considerable structural identity with one another. As described earlier, for HLA-B27 to mature into a trimolecular complex inside the endoplasmic reticulum, each heavy chain has to become associated with the monomorphic β 2m and a polymorphic peptide. These peptides are derived from proteins that are degraded in the proteasomes outside the endoplasmic reticulum and are transported into the endoplasmic reticulum, often with lengths exceeding the HLA class I peptide motif. *ERAP1* and *ERAP2* are aminopeptidases, which degrade the peptides to suitable lengths to be accommodated into the HLA class I heavy chain- β 2m complex.^{36,37} It is conceivable that alteration of the expression or the structures of these aminopeptidases can change the peptide repertoire of HLA-B27 or can lead to events postulated by the free heavy chain or the unfolded protein response hypotheses.

How Non-Major Histocompatibility Complex Genes Modify the Cytokine Network

As was described in a previous section, a major mediator of ankylosing spondylitis is TNF. TNF is situated relatively upstream mechanistically in a vast network of

arthritis-causing cytokines such as IL-1, -6, and -17.⁸ This network is a self-organizing complex kept in balance with self-regulating inhibitors. Three of the non-MHC ankylosing spondylitis genes can potentially perturb such balance in the cytokine network. The activities of two of the ankylosing spondylitis genes—*IL-1R* and *IL-23R*—are self-evident. *IL-23R* is especially appealing to the pathogenesis of ankylosing spondylitis because it leads to the generation of IL-17, a cytokine that probably holds as pivotal a position as TNF.³⁸ The other non-MHC ankylosing spondylitis gene, *ERAP1*, apparently has dual biologic activity. Its activities inside the ER have already been described earlier. When present on the cell surface, *ERAP1* aids in release of the receptors for TNF, IL-1, and IL-6.^{34,39} It is possible that polymorphisms of *ERAP1* can modify the balance of the cytokine network through this receptor-releasing activity, which favors the development of ankylosing spondylitis.

STRUCTURAL DAMAGE IN ANKYLOSING SPONDYLITIS

Previous sections on research into the pathogenesis of ankylosing spondylitis do not directly address the processes of bone destruction and bone formation. Ankylosing spondylitis (AS) is a disease that typically affects the structures of the spine and the entheses. In the spine, the areas involved are the sacroiliac joints, the vertebral bodies, and the zygapophyseal joints. Enthesitis, on the other hand, is an extra-articular manifestation defined as inflammation at the anatomic zones where ligaments or tendons insert into underlying bone. Examples include the Achilles tendon and the fascia plantaris. Less commonly, peripheral arthritis can also be present in AS patients. Synovitis and enthesitis, joint erosions, bony sclerosis, and progressive bridging of the joint space (ankylosis) characterize sacroiliac joint involvement. In the vertebral bodies, osteitis is associated with loss of trabecular bone, leading to osteoporosis and increased fracture risk.⁴⁰ Paradoxically, at the same time, new bone formation can lead to syndesmophyte formation, and eventually ankylosis is found in the same disease and the same patients. In the zygapophyseal joints, inflammation and ankylosis are also recognized. Extra-articular enthesitis is characterized by bone marrow edema and by bony spur formation. A number of features have been proposed as typical for synovitis in AS and related spondyloarthritides, as compared with other rheumatic diseases.⁴¹ These include the presence of specific macrophage subsets, neutrophils, and increased vascularity.

Both inflammation and progressive ankylosis are considered to be separate targets for therapeutic intervention. The two processes are independent of each other, but both can lead to loss of mobility in AS.⁴² In the past, most of the research attention has been focused on mechanisms of inflammation. More recently, the process of ankylosis has become a new and high-priority research target. Progressive ankylosis is highly variable between individuals and in most patients shows a fairly slow course.⁴³ Despite their success in controlling patients' symptoms, anti-TNF strategies have failed to show an inhibitory effect on spinal ankylosis.⁴⁴⁻⁴⁶ These drugs do have a positive effect on the inflammation-associated osteoporosis that can lead to vertebral fractures.⁸

The link between inflammation and ankylosis, however, remains poorly understood.

Anatomic and Molecular Bases of Ankylosis

Histomorphologic studies of the spine are relatively rare owing to difficulty in accessing the tissues. Based on studies performed decades ago, several different mechanisms of new bone formation have been proposed.⁴⁷ Both endochondral and direct bone (also known as membranous) formation appear to play a role. These two different types of bone formation have been best studied during development.⁴⁸ The process of endochondral bone formation is critical for the development of the long bones and starts with proliferation and condensation of precursor cells. These cells subsequently differentiate into chondrocytes, which produce an extracellular matrix rich in type II collagen. Articular chondrocytes appear not to further differentiate and have a stable phenotype. Developmental and growth plate chondrocytes, on the other hand, progress into hypertrophic chondrocytes. These cells produce a matrix rich in type X collagen. This matrix gets calcified, is invaded by newly forming vessels, becomes broken down, and is gradually replaced by bone with active osteoblasts as the cellular component. Membranous or direct bone formation is important for the development of the skull and for cortical bone growth.

Unlike endochondral bone formation, in membranous bone formation, progenitor cells directly differentiate into osteoblasts. In ankylosing spondylitis, the shape of the syndesmophytes and their volume suggest that endochondral bone formation is more important than membranous bone formation. However, growth factors that steer endochondral and direct membranous bone formations belong to the same families, and the differentiation process of the progenitor cells is likely determined by the specific localization of the cells and local balances between growth factors. A third process, chondroid metaplasia, has been proposed as an additional mechanism for ankylosing spondylitis. In this process, the chondrocyte matrix is calcified and thus becomes a bone-like tissue. In summary, the temporospatial relationship between inflammation and new bone formation in AS is not clear from these studies. Recent work shows that both classical innate and adaptive immune systems might also participate.⁴⁹

From the molecular perspective, most data concerning ankylosing spondylitis have been derived from mouse models. Based on the view that new bone formation will recapitulate to some extent bone development and growth, a critical role for bone morphogenetic protein (BMP) and Wnt signaling has been proposed (Figure 74-2). In a mouse model of enthesitis, Noggin, a BMP antagonist, inhibits new bone formation originating from the enthesis in peripheral joints.⁵⁰ In a human TNF transgenic mouse model of joint destruction, antibodies against DKK1, a Wnt co-receptor antagonist, reversed the arthritis phenotype from erosive to remodeling.⁵¹ Although these animal models have clear limitations, they potentially identify key mechanisms and therapeutic targets.

The specific molecular cascades involved in bone erosion and in osteoporosis in patients with AS have been even less studied. Often it is just assumed that excessive activation of osteoclasts by the receptor activator of nuclear

factor κ B (NF κ B) ligand (RANKL)-RANK system plays a critical role.

Relationship between Inflammation and New Tissue Formation

The specific phenotype of ankylosing spondylitis with progressive spinal ankylosis remains enigmatic. Other diseases such as fibrodysplasia ossificans progressiva, diffuse idiopathic skeletal hyperostosis, and sometimes osteoarthritis, are also characterized by excessive bone formation. These facts and interindividual variability among AS patients suggest that genetic factors may play a role in AS.

Specific localization of new bone formation at enthesal sites suggests that biomechanical factors may play an important role.⁵² Bony spurs are found at enthesal sites in degenerative lesions and often are associated with strain. Whether there is a direct relationship between inflammation and new bone formation remains controversial. In most experimental systems, proinflammatory cytokines inhibit chondrogenesis and osteogenesis. In other joint diseases such as rheumatoid arthritis, TNF likely contributes to inhibition of repair by upregulating antagonists of the Wnt signaling pathway such as DKK1.⁵³ Different and contrasting but not mutually exclusive hypotheses have been put forward to explain the apparent paradox of an inflammatory disease associated with new tissue formation^{47,53,54} (see Figure 74-2). Two of these support the concept that inflammation in AS can subside spontaneously, thereby leaving windows of opportunity for tissue repair ultimately leading to ankylosis. The third hypothesis proposes that chronic inflammation and progressive ankylosis are linked, but that they are in molecular terms largely independent processes. In this hypothesis, cell stress and damage at the enthesis are proposed as disease-initiating events.

It remains unclear whether very early treatment of patients with anti-TNF drugs will have an impact on structural progression. It is possible that future therapeutics based on modulation of BMP and Wnt signaling could have an additional effect on ankylosis, but given the critical role of these pathways in the homeostasis of different organs, simple antagonist or agonist approaches may have toxicity issues. The single observation that celecoxib has an effect on structural disease progression indicates that modulation of bone formation is possible.⁵⁵ In this case, it is hypothesized that this anti-inflammatory drug has a direct effect on bone formation, and that this particular effect is not linked to symptom control. A major problem in interpreting the results of therapeutic studies so far is that it is not clear which particular patients are prone to new bone formation. Research conducted to identify this specific at-risk patient group will be critical. Moreover, these efforts may lead to better insights into initiating pathophysiologic mechanisms of the disease.

PATHOGENESIS OF REACTIVE ARTHRITIS

Reactive arthritis (ReA)—a sterile synovitis precipitated by an extra-articular infection—has been a challenge for resolving pathogenesis definitively. ReA is the quintessential paradigm of host susceptibility interacting with

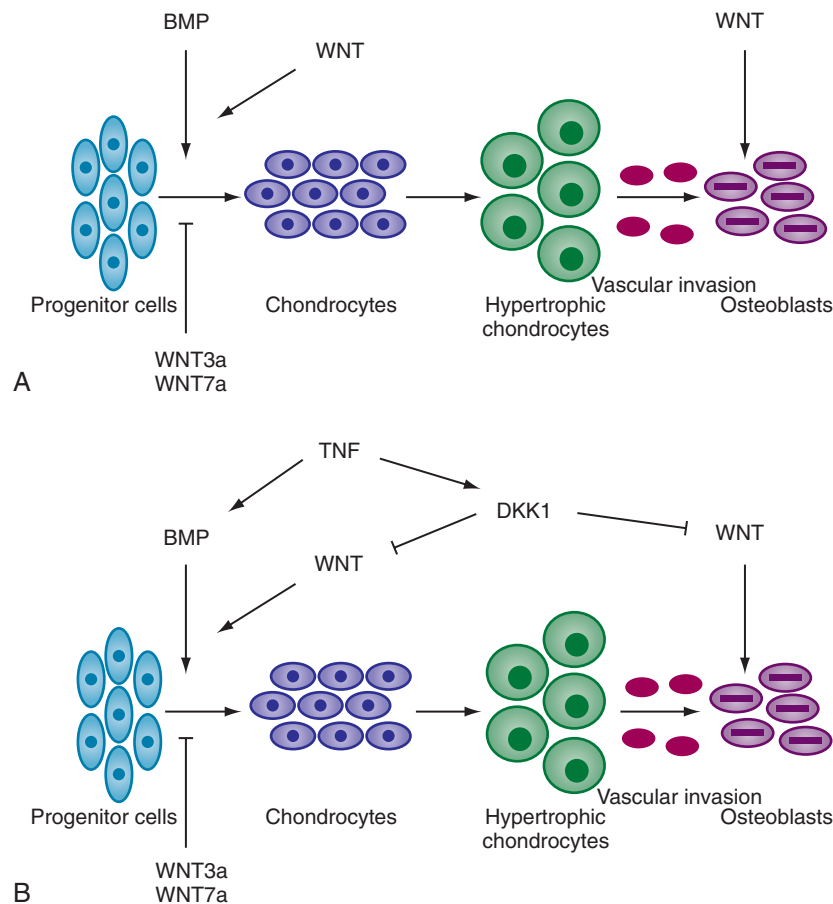

Figure 74-2 Roles of bone morphogenetic proteins (BMPs) and WNTs in endochondral bone formation. **A**, Physiologic endochondral bone formation is stimulated by BMPs. WNTs play a supportive role for BMPs. However, some WNTs have a negative effect on early chondrocyte differentiation. **B**, In the presence of inflammation, tumor necrosis factor (TNF) may stimulate BMP signaling as well as expression of DKK1, which acts as a WNT antagonist. The balance between TNF, BMP, and WNT signaling may determine the onset and progression of ankylosis.

an environmental trigger; as such, it sets a conceptual framework that underlies a broad range of rheumatic diseases. Indeed, ReA occupies an interesting middle ground between autoimmune and autoinflammatory inflammatory diseases.⁵⁶ Studies in ReA and undifferentiated oligoarthritis indicate that about 50% of such cases can be attributed to a specific pathogen by a combination of culture and serology, the predominant organisms being *Salmonella*, *Yersinia*, and *Chlamydia*.⁵⁷ Species-specific analysis of serologic responses to pathogens may further enhance this detection rate. A recent population-based study sought to define the epidemiology and clinical spectrum of ReA following culture-confirmed infection with bacterial enteric pathogens in the United States.⁵⁸ Telephone interviews were conducted with persons who had culture-confirmed *Campylobacter*, *Escherichia coli* O157, *Salmonella*, *Shigella*, or *Yersinia* infection in Minnesota and Oregon between 2002 and 2004. The estimated incidence of ReA following culture-confirmed *Campylobacter*, *E. coli* O157, *Salmonella*, *Shigella*, or *Yersinia* infection in Oregon was 0.6 to 3.1 cases per 100,000.

Cytokines in Reactive Arthritis

Analysis of T cell subsets with respect to cytokine profiles is a further method for studying the link between infection

and reactive arthritis. Exposure to different pathogens can stimulate at least two patterns of cytokine production by CD4⁺ T cells (T helper [Th]1 and Th2). Th1 cells mediate a protective role against intracellular pathogens. Thus, it would seem appropriate that these cells would be central in clinical complications of such infections. In a study of 11 patients with ReA, it was observed that stimulation of synovial fluid mononuclear cells resulted in secretion of low amounts of interferon (IFN)- γ and TNF but high amounts of IL-10.⁵⁹ IL-10 was responsible for suppression of IFN- γ and TNF as judged by the effect of adding IL-10 or anti-IL-10 to cells. Enhanced production of TNF and IFN- γ is observed in chronic ReA when compared with acute ReA or rheumatoid arthritis.⁶⁰ TNF dependence of chronic inflammation in the spine draws indirect support from the dramatic changes that follow the institution of anti-TNF therapy in these patients. A study investigated TNF production in healthy subjects with previous *Yersinia*-triggered ReA.⁶¹ The study comprised HLA-B27⁺ subjects with ReA (B27⁺ReA⁺), in contrast to B27⁺ReA⁻ and B27⁻ReA⁻ subjects. It was observed that B27⁺ReA⁺ supernatants had higher TNF levels than B27⁺ReA⁻ supernatants after stimulation with the phorbol ester, phorbol myristate acetate (PMA), and the calcium ionophore, A23187. Patients who have recovered from *Yersinia* ReA show enhanced TNF production, which may be regulated at the level of

monocyte adhesion. A recent study measured levels of several proinflammatory and immunoregulatory cytokines in synovial fluid and sera from patients with ReA and undifferentiated spondyloarthritis, in comparison with rheumatoid arthritis and osteoarthritis.⁶² Synovial fluid concentrations of IL-17, IL-6, transforming growth factor (TGF)- β , and IFN- γ were significantly higher in patients with ReA as compared with RA patients. Synovial fluid levels of IL-10 were comparable, but the ratio of IFN- γ /IL-10 was significantly higher in ReA patients than in rheumatoid arthritis patients. IL-17, IL-6, IL-10, and IFN- γ synovial fluid levels were significantly higher than paired serum levels in ReA patients. These findings suggest that Th17 cells, as well as Th1 cells, could be playing a major role in the chronic inflammation seen in ReA.

Innate Immunity and Reactive Arthritis

Recognition that critical host determinants are operational as the first line of defense against pathogens, and that these determinants precede adaptive immunity, represents a major advance in our understanding of host-microbial interactions. ReA represents the paradigm of a dynamic interaction between genetically defined host susceptibility and an environmental trigger. Thus, it is particularly relevant to examine innate immunity of the host because these events, which set the stage for the subsequent development of adaptive immunity, occur early in the course of a challenge by an arthritogenic pathogen. A recent outbreak of salmonellosis was accompanied by ReA and afforded investigators the opportunity to study genetic susceptibility to ReA, which traditionally has been difficult in examining sporadic cases of ReA.⁶³ Using this cohort and exposed non-ReA individuals as controls, a recent study examined the role of innate immunity in ReA.⁶⁴ Genotyping was performed using two TLR2 (rs5743708 and rs5743704) and two TLR4 (rs4986790 and rs4986791) SNPs. No TLR4 exon variants were associated with any clinical events accompanying the *Salmonella* infection. In contrast, one of the rare TLR2 SNPs (rs5743708; R753Q) was associated with the development of ReA. The TLR2 variant 753Q was not detected in any of the infected individuals with an uncomplicated course. Another TLR2 variant, 631H, was associated with articular symptoms in infected men. This is the first demonstration that genetic variants of TLR2, but not TLR4, are associated with clinical ReA.

The contribution of TLR interactions in *Chlamydia* has also been studied recently.⁶⁵ *Chlamydia trachomatis*-inactivated elementary bodies (EBs) and the following antigens were tested for their ability to induce the production of proinflammatory cytokines by human monocytes/macrophages and THP-1 cells: purified lipopolysaccharide, recombinant heat shock protein (rhsp)70, rhsp60, rhsp10, recombinant polypeptide encoded by open reading frame 3 of the plasmid (rpgp3), recombinant macrophage infectivity potentiator (rMip), and recombinant outer membrane protein 2 (rOmp2). Aside from EB, rMip displayed the greatest ability to induce release of IL-1 β , TNF, IL-6, and IL-8. Stimulating pathways appeared to involve TLR2/TLR1/TLR6 with the help of CD14 but not TLR4. These data support a role for Mip lipoprotein in the pathogenesis of *C. trachomatis*-induced inflammatory responses and

heighten attention on innate immunity during *Chlamydia* infection.

Response of Reactive Arthritis to Antibiotic Treatment

Recognition that *C. trachomatis* and *C. pneumoniae* species may exist in a persistent metabolically active infective state in the synovium has suggested that persistent chlamydiae may be susceptible to antimicrobial agents. A recent study undertook a 9-month, double-blind prospective trial to assess a 6-month course of combination antibiotics as treatment for *Chlamydia*-induced ReA.⁶⁶ Treatment arms consisted of doxycycline and rifampin, azithromycin and rifampin, and placebo. After 6 months of treatment, 17 of 27 subjects (63%) on antibiotics were responders compared with 3 of 15 (20%) on placebo. Antibiotic treatment was associated with significant improvement in the modified swollen joint count and tender joint count. Significantly more subjects became polymerase chain reaction negative at month 6 in the active therapy group than in the placebo group. These data suggest that a 6-month course of combination antibiotics might serve as effective therapy for chronic *Chlamydia*-induced ReA. Further studies will be needed to determine whether this approach is effective in ReA triggered by other pathogens.

Ankylosing Spondylitis

SJEF M. VAN DER LINDEN •
DOMINIQUE BAETEN •
WALTER P. MAKSYMOWYCH

KEY POINTS

The concept of axial spondyloarthritis comprises both nonradiographic axial disease and ankylosing spondylitis (AS) according to the modified New York criteria.

Magnetic resonance imaging of the sacroiliac joints may show inflammation before structural changes appear on conventional radiographs. The modified New York criteria are useful primarily to classify groups of patients (e.g., for clinical or epidemiologic studies). They are not well suited to establish the diagnosis of AS in individual patients.

Nonradiographic axial spondyloarthritic disease occurs about twice as often as AS by modified New York criteria and may show comparable disease activity.

Inflammatory back pain is the usual clue to the early diagnosis of AS and axial spondyloarthritis.

In many populations, AS occurs in 1% to 3% of HLA-B27–positive individuals. The disease is more common (about 10%) among first-degree relatives of HLA-B27–positive AS patients.

Among patients with chronic inflammatory back pain, HLA-B27 typing may aid in establishing the diagnosis of AS and axial spondyloarthritis.

Group physiotherapy is more effective than exercises performed at home by the patient.

Expert opinion and BASDAI (Bath ankylosing spondylitis disease activity index) greater than 4 (scale 0 to 10) are important in considering tumor necrosis factor (TNF)-blocking agents if conservative therapy with nonsteroidal anti-inflammatory drugs and physiotherapy fails.

Most AS patients have a normal or marginally elevated erythrocyte sedimentation rate and C-reactive protein level. Patients with normal levels of acute-phase reactants tend to have a somewhat lower response to anti-TNF agents.

Ankylosing spondylitis (AS) belongs to the group of diseases known as the *spondyloarthropathies* or, better, *spondyloarthritides*. This group of disorders constitutes a family of related but heterogeneous conditions rather than a single disease with different clinical manifestations¹ (Tables 75-1 and 75-2).

Radiographic sacroiliitis is considered a hallmark in AS and is found in more than 90% of patients. The inflammation of the sacroiliac (SI) joints and the spine eventually may lead to bony ankylosis. The term *ankylosing spondylitis* is derived from the Greek roots *ankylos*, or “bent” (although it now usually implies fusion or adhesions), and *spondylos*, or “vertebral disk.” Ankylosis of the spine tends to appear

in late stages of the disease and does not occur in many patients with mild disease.

Many patients with AS have onset of back pain during their third decade of life. It takes, on average, 6 to 8 years between the onset of back pain and establishing a definite diagnosis of AS. This diagnostic delay in the majority of patients results mainly from the relatively late appearance of definite radiographic sacroiliitis on conventional plain radiographs,^{2,3} which is a requirement for diagnosis according to the modified New York criteria. Active sacroiliitis on magnetic resonance imaging (MRI) has been shown to predict the later appearance of sacroiliitis on radiographs.^{4,5} Thus many patients at an early stage of AS typically present with characteristic clinical symptoms of AS but may not show definite sacroiliitis on radiographs. Therefore they may not be classified as AS cases. In such patients with suspected early AS, sacroiliitis may best be detected on MRI.³ It has been proposed that a substantial proportion of such patients will develop radiographic sacroiliitis (i.e., structural damage of SI joints) with time and will progress to definite AS, but this hypothesis requires further evaluation in prospective studies. On the other hand, this also implies that a proportion of patients will remain at this (nonradiographic) stage of disease, with inflammation on MRI at some point, but without radiographically detectable damage over the subsequent years.⁵ Therefore in order to describe these patients correctly, the term *early AS* has been dropped, with terms such as *preradiographic axial spondyloarthritis*³ or, more recently, *nonradiographic axial spondyloarthritis*⁶ seeming to be more appropriate (Figure 75-1). The term *axial spondyloarthritis* comprises both nonradiographic AS and classic AS (according to the modified New York criteria) and is now considered by ASAS (Assessment of SpondyloArthritis international Society) as the preferred terminology for patients with predominantly spinal disease. The total prevalence of axial spondyloarthritis has been estimated at two to three times that of AS according to the modified New York criteria.⁷ In the concept of axial spondyloarthritis, the disease AS represents the tip of the iceberg. Patients with axial spondyloarthritis who have normal SI joints on conventional radiographs often show inflammatory changes on appropriate MRI and may or may not progress to sacroiliitis according to the New York criteria. Such patients may have active disease that needs appropriate treatment. They respond to therapy with biologics. The course and natural history of axial spondyloarthritis without radiographic sacroiliitis is not yet well known. However, although this chapter focuses on radiographic AS, many aspects also apply to patients with axial spondyloarthritis. The interval between the first complaints of the disease and the time of a definite diagnosis may be as long

Table 75-1 Spondyloarthritis

Reactive arthritis
Arthropathy of inflammatory bowel disease (Crohn's disease, ulcerative colitis)
Psoriatic arthritis
Undifferentiated spondyloarthropathies
Juvenile chronic arthritis and juvenile-onset ankylosing spondylitis

as 4 to 9 years.⁸ This affects how disease duration is defined. Important components of the definition of disease duration are provided in Table 75-3.⁹

CLASSIFICATION

Criteria for Ankylosing Spondylitis and Axial Spondyloarthritis

The diagnosis of AS is based on clinical features. The disease is “primary” or “idiopathic” if no associated disorder is present; it is “secondary” if the disease is associated with psoriasis or chronic inflammatory bowel disease. In daily practice, a presumptive clinical diagnosis of AS is usually supported by evidence of sacroiliitis on conventional pelvic radiographs; indeed, many think of AS as symptomatic sacroiliitis. The presence of sacroiliitis does not necessarily indicate the presence of AS, however. Moreover, although radiographic sacroiliitis is frequent in AS, it is by no means an early or obligate manifestation of the disease.¹⁰ Contrary to the New York criteria, radiographic evidence of sacroiliitis is not obligatory to fulfill the Rome criteria (Table 75-4). Both sets were primarily intended for use in epidemiologic studies. Lack of either sensitivity or specificity led to a modification of the New York criteria for AS¹¹ (see Table 75-4). Two criteria—limitation of lumbar spine motion and limitation of chest expansion—appear to reflect disease duration; they are usually not present in early disease.¹² It should be stressed that classification criteria are usually not useful for early diagnosis owing to a lack of sensitivity. In particular, in the early phase of AS, conventional SI radiographs may be normal. MRI is useful to diagnose the disease with predominantly axial manifestations before the presence of radiographic sacroiliitis.¹³ To encompass both pre-radiographic AS and classic AS (according to the modified New York criteria), the Assessment of SpondyloArthritis international Society (ASAS) has proposed classification criteria for axial spondyloarthritis for patients with back pain of at least 3 months' duration and age at onset of complaints before 45 years (Table 75-5). The term *axial spondyloarthritis* has been introduced as an umbrella for the

Figure 75-1 Concept of axial spondyloarthritis as an umbrella for patients without radiographic damage and patients with such damage. MRI, magnetic resonance imaging.

entire spectrum of spondyloarthritis patients with predominant axial involvement, irrespective of the presence of structural damage on radiographs. Thus axial spondyloarthritis includes nonradiographic axial spondyloarthritis and classical AS (fulfilling the modified New York criteria). According to the ASAS classification criteria for axial spondyloarthritis,⁷ a patient with chronic back pain and age at onset before age 45 can be classified as having axial spondyloarthritis if sacroiliitis on imaging (radiographs or MRI) is present plus at least one further spondyloarthritic feature, or, in the absence of sacroiliitis on imaging, if *HLA-B27* plus at least two further spondyloarthritis features are present (see Table 75-5). The sensitivity of the entire set of ASAS criteria for axial spondyloarthritis was 83%, and the specificity was 84%.⁷ In the ASAS study on these new criteria, 30% of all patients diagnosed as having axial spondyloarthritis had definite radiographic sacroiliitis and fulfilled the modified New York criteria for AS. Therefore two-thirds were classified as nonradiographic axial spondyloarthritis.⁷

EPIDEMIOLOGY

Prevalence

The prevalence of AS closely parallels the frequency of *HLA-B27*. This holds true for those B27 subtypes that are associated with the disease, but it is not true for populations in which the *HLA-B27*06* subtype that lacks a strong association with AS occurs frequently such as the Indonesian population.¹⁴⁻¹⁶

Table 75-2 Clinical Characteristics of Spondyloarthritis

Typical pattern of peripheral arthritis—predominantly of lower limb, asymmetric
Absence of rheumatoid factor
Absence of subcutaneous nodules and other extra-articular features of rheumatoid arthritis
Overlapping extra-articular features characteristic of the group (e.g., anterior uveitis)
Significant familial aggregation
Association with <i>HLA-B27</i>

Table 75-3 Components of Disease Duration

Onset of axial AS manifestations (inflammatory back pain)
Onset of extra-axial AS manifestations (peripheral arthritis, enthesitis)
Onset of associated spondyloarthropathic diseases (acute anterior uveitis, inflammatory bowel disease, psoriasis)
Time since diagnosis of AS by health care provider

AS, ankylosing spondylitis.

Table 75-4 Criteria for Ankylosing Spondylitis

Rome, 1961
Clinical Criteria
1. Low back pain and stiffness for more than 3 mo, not relieved by rest
2. Pain and stiffness in thoracic region
3. Limited motion in lumbar spine
4. Limited chest expansion
5. History or evidence of iritis or its sequelae
Radiographic Criterion
6. Radiograph showing bilateral sacroiliac changes characteristic of ankylosing spondylitis (this excludes bilateral osteoarthritis of sacroiliac joints)
Definite Ankylosing Spondylitis
Grade 3 or 4 bilateral sacroiliitis with at least one clinical criterion Or At least four clinical criteria
New York, 1966
Diagnostic Criteria
1. Limitation of lumbar spine motion in all three planes: anterior flexion, lateral flexion, extension
2. Pain at dorsolumbar junction or in lumbar spine
3. Limitation of chest expansion to 2.5 cm or less measured at level of fourth intercostal space
Grading of Radiographs
Normal, 0; suspicious, 1; minimal sacroiliitis, 2; moderate sacroiliitis, 3; ankylosis, 4
Definite Ankylosing Spondylitis
Grade 3 or 4 bilateral sacroiliitis with at least one diagnostic criterion Or Grade 3 or 4 unilateral or grade 2 bilateral sacroiliitis with diagnostic criterion 1 or with criteria 2 and 3
Probable Ankylosing Spondylitis
Grade 3 or 4 bilateral sacroiliitis with no diagnostic criteria
Modified New York, 1984
Criteria
1. Low back pain of at least 3 months' duration improved by exercise and not relieved by rest
2. Limitation of lumbar spine in sagittal and frontal planes
3. Chest expansion decreased relative to normal values for age and sex
4. Bilateral sacroiliitis grade 2 to 4
5. Unilateral sacroiliitis grade 3 or 4
Definite Ankylosing Spondylitis
Unilateral grade 3 or 4, or bilateral grade 2 to 4 sacroiliitis and any clinical criterion

Data from van der Linden SM, Valkenburg HA, Cats A: Evaluation of diagnostic criteria for ankylosing spondylitis: a proposal for modification of the New York criteria, *Arthritis Rheum* 27:361–368, 1984.

Among whites, the estimated prevalence rate of AS as defined by the modified New York criteria ranges from 68 per 100,000 population older than 20 years in the Netherlands to 197 per 100,000 in the United States.^{8,17} The prevalence of clinical AS in France is 150 per 100,000 adults, whereas in Norway it is 210 per 100,000 adults.^{18,19} The prevalence of the disease in Finland is similar, with a figure of 150 per 100,000 people.²⁰

Higher prevalence rates have been reported in central Europe. An epidemiologic study from Berlin reported a

prevalence figure of 0.86%.²¹ In the general population, AS is likely to develop in about 1% to 2% of HLA-B27⁺ adults who have a disease-associated B27 subtype, although there may be regional or geographic differences. For example, in northern Norway, AS may develop in 6.7% of HLA-B27⁺ people.^{8,22}

The disease is much more common among HLA-B27⁺ first-degree relatives of HLA-B27⁺ AS patients; roughly 10% to 30% of them have signs or symptoms of AS.⁸ In fact, a positive family history of AS is a strong risk factor for the disease.

Incidence

There is no adequate evidence that the incidence of AS has changed in the past few decades. Clinical features, age of onset, and survival time have remained stable.²³ One study revealed an overall age and gender-adjusted incidence of 7.3 per 100,000 person-years. This U.S. figure compares quite well with the Finnish study, which revealed a stable incidence of 8.7 (95% confidence interval [CI], 6.4 to 11.0) per 100,000 people aged 16 or older.¹⁸

Racial Distribution

AS occurs in all parts of the world, but there are race-related differences in prevalence. This might reflect differences in the distribution of HLA-B27 among races. Approximately 90% of white patients with AS possess HLA-B27, whereas AS and HLA-B27 are nearly absent (prevalence of B27 < 1%) in African blacks and Japanese. In African-Americans, owing to racial admixture with whites, 2% possess B27, but only about 50% of black patients with AS possess B27. Correspondingly, African-Americans are affected far less frequently than American whites.

Table 75-5 ASAS Classification Criteria for Axial Spondyloarthritis (SpA) (in Patients with Back Pain ≥ 3 Months and Age at Onset < 45 Years)

Sacroiliitis on imaging plus ≥1 SpA feature	OR	HLA-B27 plus ≥2 other SpA features
SpA Features		Sacroiliitis on Imaging
Inflammatory back pain		Active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA
Arthritis		OR
Enthesitis (heel)		Definite radiographic sacroiliitis according to modified New York criteria
Uveitis		
Dactylitis		
Psoriasis		
Crohn's disease/ulcerative colitis		
Good response to NSAIDs		
Family history for SpA		
HLA-B27		
Elevated CRP*		

*Elevated CRP is considered a SpA feature in the context of chronic back pain.

ASAS, Assessment of SpondyloArthritis international Society; CRP, C-reactive protein; HLA-B27, human leukocyte antigen-B27; IBP, inflammatory back pain; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs.

From Kollinger S, Bird LA, Roddis M, et al: HLA-B27 heavy chain homodimers are expressed in HLA-B27 transgenic rodent models of spondyloarthritis and are ligands for paired Ig-like receptors, *J Immunol* 173:1699–1710, 2004; and Rudwaleit M: New classification criteria for spondyloarthritis, *Int J Adv Rheumatol* 8:1–7, 2010.

Burden of Disease

AS is associated with a considerable burden to the patient and society. Apart from the axial and articular manifestations, extra-articular manifestations such as enthesitis and acute anterior uveitis and comorbidities such as inflammatory bowel disease and psoriasis contribute to the burden of disease. In addition, a large proportion of patients has spinal osteoporosis, leading to vertebral fractures and thoracic kyphosis. All these features result in a decreased quality of life. Disease status scores for physical functioning and disease activity correlate clearly with psychologic scores for anxiety and depression.²⁴ The impact of AS can also be seen in various aspects of employment, ranging from requiring assistance at work to increased sick leave and withdrawal from the workforce.^{25,26} Apart from the impact on labor force participation, AS patients have an important impact on health care and non-health care resource utilization, resulting in mean total costs (direct and productivity) of about \$6700 to \$9500 per year per patient when applying the human capital approach to calculate productivity costs.²⁷⁻²⁹

The burden of illness increases with duration of disease. Because the burden due to AS reduces quality of life, and because all types of costs associated with AS result from loss of function and disease activity, early diagnosis and treatment are necessary to prevent or reduce functional decline and improve patient outcome.³⁰

PATHOGENESIS

The precise cause of AS is still unclear, but several novel insights are currently emerging. First, several new hypotheses have been proposed to explain the major genetic contribution of HLA-B27. Second, other genetic risk factors have been identified by genome-wide association studies. Third, there is increasing evidence that AS may be driven by abnormal innate immune reactions rather than by autoantigen-specific T and/or B cell reactivity. And finally, the molecular mechanisms of new bone formation and their relationship with inflammation have started to emerge.

HLA-B27

The dominant role of genetic factors is highlighted by data demonstrating disease concordance in 75% of monozygotic twins compared with 13% of nonidentical twins,³¹ familial aggregation,³² and population data demonstrating associations with HLA-B27.³³ About 90% of white AS patients are HLA-B27⁺. HLA-B27 is the first described and major genetic risk factor for AS but, despite the near-pervasive nature of this association, it has been estimated that B27 contributes only 16% of the total genetic risk. In humans, there appears to be a hierarchy of association of the more than 45 as yet known subtypes of HLA-B27 with AS, ranging from strong association with HLA-B*2705 to weak association with HLA-B*2709. The direct pathogenic role of HLA-B27 is evidenced by the spontaneous spondyloarthritis-like disease in rats overexpressing HLA-B27.³⁴⁻³⁶

The main function of human leukocyte antigen (HLA) class I molecules such as HLA-B27 is to present peptides to CD8⁺ T cells and, accordingly, the arthritogenic peptide

hypothesis proposes that CD8⁺ T cells are activated by bacterial antigens, for example in the gut, and after recirculation are reactivated in the joint by cartilage or other autoantigens. A number of studies have provided some partial evidence for this concept.^{37,38} This hypothesis has been thoroughly questioned by the fact that HLA-B27 transgenic rats develop severe spondyloarthritis-like disease even in the absence of CD8⁺ T cells.^{39,40} Two alternative hypotheses have been proposed more recently, suggesting that HLA-B27 has other specific features independent of antigen presentation that may directly contribute to disease. One theory indicates that HLA-B27 has a special tendency to form heavy chain homodimers that, when present on the cell surface, can trigger direct activation of natural killer (NK) cells through recognition via killer immunoglobulin receptor (KIR)-like receptors.^{41,42}

Alternatively, HLA-B27 has a special propensity to misfold in the endoplasmic reticulum and thereby to promote an unfolded protein response, which in turn modulates the functional behavior and cytokine production of myeloid cells.⁴³⁻⁴⁵

The latter two hypotheses imply a role for altered innate immune responses rather than autoantigen-driven acquired immunity in the pathogenesis of AS.

Population and family studies have shown that HLA-B60 increases susceptibility to AS.⁴⁶ This applies to both HLA-B27⁺ and HLA-B27⁻ persons.

Non-Human Leukocyte Antigen Genes

Two observations clearly suggest a role for non-HLA genetic risk factors. First, there is an increased risk for disease in B27⁺ first-degree relatives of AS probands (10% to 20%) compared with B27⁺ individuals in the general population (2% to 5%).⁸ Second, disease concordance is 75% in identical twins versus 27% in HLA-B27 concordant dizygotic twins.³¹ Genome-wide association studies have now allowed the identification of several of these factors.^{47,48} There is a robust association with single-nucleotide polymorphisms (SNPs) in endoplasmic reticulum aminopeptidase-1 (ERAP-1), an enzyme involved in the trimming of peptides for loading in MHC molecules. There is now emerging evidence for a gene-gene interaction between ERAP-1 and HLA-B27, but it remains unknown how the polymorphisms may affect antigen presentation, HLA-B27 homodimer formation, and misfolding. A second strong association is found with SNPs in IL-23R, a genetic feature shared with Crohn's disease and psoriasis. Together with the suggested but not yet confirmed association with STAT3⁴⁹ and JAK2 polymorphisms, this suggests the potential involvement of an interleukin (IL)-17 response in AS. Definite association was also found with gene deserts on chromosome 2p15 and 21q22, which warrants further investigation of noncoding ribonucleic acid (RNA) and epigenetic effects in the pathophysiology of this disease. Besides these definite associations, genome-wide association studies have suggested potential associations with tumor necrosis factor (TNF) receptor 1 (TNFR1), the signaling molecule TNFR1-associated death domain protein (TRADD), the TNF superfamily cytokine TNFSF15, IL-1A and the IL-1 receptor 2 (IL-1R2), IL-12B, the vascular morphogenesis protein gene anthrax toxin receptor 2 (ANTXR2), and the innate

immune receptor caspase recruitment domain family, member 9 (CARD9).⁵⁰

These associations point toward a potential pathogenic role for altered innate immune responses, TNFR1 signaling, and IL-1.

The importance of TNF to the pathogenesis of AS is highlighted in the phenotype of a transgenic mouse model that overexpresses TNF. These animals develop sacroiliitis characterized by the formation of osteoclasts and granulation tissue.

Autoimmunity versus Autoinflammation

Both the alternative roles for HLA-B27 besides antigen presentation and the genetic risk factors suggest that AS may not be primarily driven by a canonical autoantigen-specific T and/or B cell reactivity. Indeed, AS does not share genetic risk factors such as PTPN22 or cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) with other autoimmune diseases and lacks disease-specific autoantibodies. On the basis of the predilection of the disease for sites rich in cartilage, it has been proposed that cartilage antigens may be the primary target of an autoimmune response in AS. This hypothesis is supported by several animal models of peripheral and axial arthritis on the basis of the induction of autoimmunity to antigens present in cartilage and fibrous tissue such as aggrecan and versican.^{51,52} T cell responses toward the G1 domain of aggrecan have also been observed in human AS, but similar responses were seen in other inflammatory joint disorders, implying a non-specific response to joint damage.⁵³ Finally, biologic therapies targeting B (such as anti-CD20) or T (such as CTLA4-Ig) cell pathways have limited to no efficacy in AS in proof-of-concept trials.^{54,55} Taken together, little strong evidence supports a primary T cell- or B cell-driven autoimmune process in AS.

An alternative hypothesis proposes that AS would be driven by abnormal reactivity of innate immune cells such as macrophages, neutrophils, and mast cells. This hypothesis is supported by several lines of evidence. First, genetic associations with CARD9 and the IL-1 pathway strongly suggest involvement of the inflammasome. Second, histologic studies demonstrated increased infiltration with innate immune cells, but not T, B, or dendritic cells in the peripheral joint and gut of patients with AS.⁵⁶⁻⁵⁸ Third, human AS and its experimental models have a predilection for sites exposed to either microbial or mechanical stress. The latter aspect has led to the concept that AS and other forms of spondyloarthritis are primarily characterized by inflammation of the so-called synovio-entheseal complex.⁵⁹ In this perspective, it is interesting to note that the fibrocartilage protein versican, which could be released during mechanical stress and induces spondylitis in BALB/c mice, is also a ligand for the innate immune receptor TLR2. Formal proof that innate immune alterations may trigger AS remains, however, awaited.

Independently of the exact origin of the inflammation, it is clear that several proinflammatory cytokines are pivotal in the downstream effector mechanisms. TNF plays a crucial role in the disease process as evidenced by the successful introduction of TNF blockade for this disease. Accordingly, transgenic overexpression of TNF in mice leads not only to

severe, destructive polyarthritis but also to sacroiliitis.⁶⁰ However, it remains incompletely understood which cells are the main producers of TNF in AS, in which form (soluble vs. transmembrane) and through which receptor (TNFR1 or TNFR2) TNF exerts its pathogenic effects, and which are the main target cells. In line with the genetic data, experimental data suggest a role for TNFR1 signaling in stromal cells.⁶¹ Besides TNF, the genetic data and emerging data from functional studies on the unfolded protein response implicate IL-23 and thus possibly IL-17 as important cytokines in the pathogenesis of AS.⁶²

Clinical trials targeting the IL-23/IL-17 pathway in AS are currently being performed.

Structural Remodeling and Ankylosis

A crucial and largely unexplained aspect of the pathogenesis of AS is the occurrence of structural remodeling and new bone formation, ultimately leading to ankylosis. Human and experimental studies have revealed three important concepts. First, the remodeling phenotype of AS cannot be explained by the absence of joint destruction because erosive disease is evidenced by histology and radiology and because the cellular and molecular machinery for cartilage and bone destruction is present and operative at the sites of disease.^{63,64}

Second, structural remodeling and osteoproliferation are dependent on endochondral bone formation. This process is governed by several molecular pathways including bone morphogenetic protein (BMP) and Wnt signaling.^{65,66}

There is emerging evidence that several inhibitors of the Wnt pathway are dysfunctional in human spondyloarthritis and that this correlates with new bone formation.⁶⁷ Third, osteoproliferation is not critically dependent on inflammation because, despite clinical efficacy on signs and symptoms, TNF blockade fails to halt radiologic progression in AS and both processes can be uncoupled in experimental models.^{68,69}

On the other hand, vertebral sites showing signs of inflammation at baseline have a higher risk for subsequent osteoproliferation on follow-up.⁷⁰ The exact relationship between inflammation and osteoproliferation needs to be further clarified because it may have important consequences for treatment.

PATHOLOGY

Characteristic pathologic features of AS include inflammation in axial joints, large peripheral joints, and entheses associated with inflammation in subchondral bone marrow. Reparation is also characteristic in terms of the development of chondroid metaplasia, followed by calcification of cartilage and formation of bone, particularly in the axial joints. Fat metaplasia in the axial skeleton at sites of prior inflammation is frequently observed on MRI.

Axial Skeleton

Detailed histopathologic studies of axial involvement in AS are limited owing to the inaccessibility of biopsy material of both SI joints and the spine. A controlled study of SI biopsies from AS patients at various stages of disease and

controls showed cellular infiltration with lymphocytes, macrophages, and plasma cells in the synovium and subchondral marrow as the earliest features of disease.⁷¹ Later features include the development of pannus extending from both synovium and subchondral bone marrow, with erosion of articular cartilage and its replacement by granulation tissue. Osteoclast formation and erosion of subchondral bone account for the typical widening of the joint spondyloarthritis seen on plain radiography. Enthesitis is also evident in later stages of disease at the insertion of the posterior capsule. Reparative changes include cartilage metaplasia at sites of active inflammation, followed by its calcification and then replacement by endochondral bone, leading to obliteration of the joint space by ankylosis. Pararticular changes include bone sclerosis and fat replacement of bone marrow. Regarding the spine, pathologic data are limited except for a number of recent studies of apophyseal joints. Immunohistologic analysis shows subchondral lymphocyte infiltrates with CD4⁺ and CD8⁺ T cells, together with hypervascularization and foci of CD68⁺ osteoclastic cells.⁷²

Peripheral Skeleton

Regarding peripheral joint manifestations of AS, histopathologic studies have assessed surgical samples of affected hip joint, synovial biopsies of knee and ankle joint, and enthesitis. Involvement of the hips is characterized by subchondral granulation tissue and osteoclast formation in the femoral heads and acetabulum that is associated with degradation of overlying articular cartilage.⁷³ Synovial studies have revealed that the type of inflammation is strongly different from that observed in RA, with increased vascularity, increased infiltration with innate immune cells, and absence of specific features of T and B cell autoimmunity.⁷⁴⁻⁷⁷

Interestingly, these studies revealed a similar pattern of inflammation in AS in comparison with other subtypes of spondyloarthritis.⁷⁸

Enthesal involvement most frequently occurs at sites rich in fibrocartilage such as the Achilles tendon. Inflammation and chronic cellular infiltration of soft tissues are relatively sparse but may be extensive within the adjacent subchondral bone, particularly in B27⁺ individuals.⁷⁹ A comparative study of the subchondral marrow from knee and hip joint entheses showed that AS patients clearly differ from those with RA and osteoarthritis with respect to the frequency of marrow inflammation, infiltration with CD8⁺ T cells, and presence of hyperosteoclastic erosive lesions.

CLINICAL MANIFESTATIONS

Skeletal Manifestations

Low Back Pain and Stiffness

Back pain is an extremely common symptom, occurring in up to 80% of the general population. Therefore it is important to note that back pain in AS and axial spondyloarthritis has special features that differentiate it from mechanical back pain⁸⁰⁻⁸² (Table 75-6). In clinical practice inflammatory back pain is often not well recognized.⁸³ Back pain is the most prevailing diagnostic feature of AS (Table 75-7).

Table 75-6 Aspects of Inflammatory Back Pain in Ankylosing Spondylitis and Axial Spondyloarthritis

Onset of complaints before age 45
Duration of symptoms more than 3 mo (chronic pain)
Located at the lower back
Alternating buttock pain
Awakening due to back pain during the second half of the night
Morning stiffness for at least 30 min
Insidious onset of complaints
Improvement with exercises
No improvement of back pain with rest
Improvement with use of nonsteroidal agents

The pain is initially felt primarily deep in the gluteal region, is dull in character, is difficult to localize, and is insidious in onset. The pain can be severe at this early phase of the disease; it localizes in the SI joints but is occasionally referred toward the iliac crest or greater trochanteric region or down the dorsal thigh. Radiation of buttock pain may suggest root compression of the sciatic nerve. The buttock pain typically alternates from side to side. Coughing, sneezing, or other maneuvers that cause a sudden twist of the back may accentuate pain. Although the pain is often unilateral or intermittent at first, within a few months it usually becomes persistent and bilateral and the lower lumbar area becomes stiff and painful. The pain is associated with a feeling of low back stiffness that is worse in the morning and may awaken the patient from sleep, particularly during the second half of the night. Many patients do not differentiate between low back pain and stiffness. The morning stiffness may last up to 3 hours. Both the stiffness and the pain tend to be eased by a hot shower, an exercise program, or physical activity; they do not improve with rest. Fatigue as a result of chronic back pain and stiffness may be an important problem and can be accentuated by sleep disturbances due to these symptoms.

Chest Pain

With subsequent involvement of the thoracic spine (including costovertebral and costotransverse joints) and the occurrence of enthesitis at the costosternal and manubriosternal joints, patients may experience chest pain accentuated by coughing or sneezing, which is sometimes characterized as “pleuritic.” The chest pain is often associated with tenderness over the sternocostal or costosternal junctions. Mild to moderate reduction of chest expansion is often detectable in an early stage of AS. Chest pain occurs relatively often in HLA-B27⁺ relatives, even in the absence of radiographic evidence of sacroiliitis.⁸⁴

Table 75-7 Diagnostic Features of Ankylosing Spondylitis

Chronic inflammatory spinal pain
Chest pain
Alternate buttock pain
Acute anterior uveitis
Synovitis (predominantly of lower limbs, asymmetric)
Enthesitis (heel, plantar)
Radiographic sacroiliitis
Positive family history of ankylosing spondylitis
Chronic inflammatory bowel disease
Psoriasis

Tenderness

Extra-articular tenderness at certain loci is a prominent complaint in some patients. These lesions are due to enthesitis. Common tender sites are the costosternal junctions, spinous processes, iliac crests, greater trochanters, ischial tuberosities, tibial tubercles, and heels (Achilles tendinitis or plantar fasciitis). Radiographically, bone spurs may develop at these sites.

Joints

The girdle or “root” joints (hips and shoulders) are the most frequently involved extra-axial joints in AS, and pain in these areas is the presenting symptom in up to 15% of patients. Shoulder involvement, but especially hip involvement, may cause considerable physical disability. Coexisting disease in the lumbar spine often contributes significantly to disability of the lower extremities. Hips and shoulders are involved at some stage of disease in up to 35% of patients. Hip disease is more common in Algeria, India, and Mexico. It is relatively more common as a presenting manifestation if the disease starts in childhood (juvenile AS). In boys 8 to 10 years of age, hip disease as a manifestation of juvenile AS is the most frequent type of chronic arthritis. These children with hip disease are mostly HLA-B27⁺, and they are serologically negative for antinuclear antibodies.

The knee joint may also be affected in AS, often as an intermittent effusion. The temporomandibular joint is involved in about 10% of patients.

Extraskkeletal Manifestations

Constitutional symptoms such as fatigue, weight loss, and low-grade fever occur frequently. Other extraskkeletal manifestations are more localized.

Eye Disease

Acute anterior uveitis or iridocyclitis is the most common extra-articular manifestation of AS, occurring in 25% to 30% of patients at some time during the course of the disease. There is no clear relationship between activity of the articular disease and this extra-articular manifestation. The onset of eye inflammation is usually acute and typically unilateral, but the attacks may alternate. The eye is red and painful, with visual impairment. Photophobia and increased lacrimation may be present. If the eye remains untreated or if treatment is delayed, posterior synechiae and glaucoma may develop. Most attacks subside in 4 to 8 weeks without sequelae if early treatment is provided. Acute anterior uveitis is more common in B27⁺ than B27⁻ patients with AS.⁸⁵ Relatives who have acute anterior uveitis seem to be at higher risk for AS. The calculated incidence of acute anterior uveitis in a Swiss family study was 89 attacks per 1000 patient-years for AS patients, but only 8 per 1000 person-years among healthy B27⁺ relatives.⁸⁶

Cardiovascular Disease

Cardiac involvement may be clinically silent or may cause considerable problems. Manifestations of cardiac

involvement include ascending aortitis, aortic valve incompetence, conduction abnormalities, cardiomegaly, and pericarditis. In rare situations, aortitis may precede other features of AS. Aortic incompetence was noted in 3.5% of patients who had the disease for 15 years and in 10% after 30 years.⁸⁷ Inflammation and dilation of the aorta are the main causes of aortic valve incompetence. Cardiac conduction disturbances are seen with increasing frequency with the passage of time, occurring in 2.7% of those with disease of 15 years' duration and in 8.5% after 30 years.⁸⁷ Both aortic incompetence and cardiac conduction defects occur twice as often in patients with peripheral joint involvement. In AS the prevalence of myocardial infarction is increased (4.4% in AS patients compared with 1.2% in the general population in a Dutch study).⁸⁸

Pulmonary Disease

Lung involvement is a rare and late manifestation of AS. It is characterized by slowly progressive fibrosis of the upper lobes of the lungs, appearing, on average, 2 decades after the onset of AS. Patients may complain of cough, dyspnea, and sometimes hemoptysis.⁸⁹

High-resolution computed tomography (CT) may be helpful in detecting interstitial lung disease in patients with respiratory symptoms whose chest radiographs are normal.⁹⁰ This imaging technique reveals a high prevalence of lung changes even among AS patients with early disease and without respiratory symptoms. The clinical significance of these findings is unknown. Long-term prospective studies need to be performed.⁹¹

Pulmonary ventilation is usually well maintained; an increased diaphragmatic contribution helps compensate for chest wall rigidity, which is due to involvement of the thoracic joints in the inflammatory process. Vital capacity and total lung capacity may be moderately reduced as a consequence of the restricted chest wall movement, whereas residual volume and functional residual capacity are usually increased.

Neurologic Involvement

Neurologic complications of AS can be caused by fracture, instability, compression, or inflammation. Traffic accidents or minor trauma can cause spinal fractures. The C5-C6 or C6-C7 level is the most commonly involved site.

As in RA, atlantoaxial joint subluxation, atlanto-occipital subluxation, and upward subluxation of the axis may occur in AS as a consequence of instability resulting from the inflammatory process. Spontaneous anterior atlantoaxial subluxation is a well-recognized complication in about 2% of patients and manifests with or without signs of spinal cord compression. It is observed more commonly in patients with spondylitis and peripheral arthritis than in those with exclusively axial involvement.⁹²

Causes of neurologic complications due to compression include ossification of the posterior longitudinal ligament (which may lead to compressive myelopathy), destructive intervertebral disk lesions, and spinal stenosis.

The cauda equina syndrome is a rare but serious complication of long-standing AS. The syndrome affects lumbosacral nerve roots. This gives rise to pain and sensory loss, but

frequently there are also urinary and bowel symptoms. Gradual onset of urinary and fecal incontinence, impotence, saddle anesthesia, and occasionally loss of ankle jerks occurs. Motor symptoms, if present, are usually mild. CT and MRI allow the accurate noninvasive diagnosis of this complication of AS.⁹³ No compressive lesions exist. Arachnoiditis and arachnoid adhesions may be important in the pathogenesis.

Renal Involvement

IgA nephropathy has been reported in many patients with AS. These patients often have an elevated immunoglobulin (Ig)A level (93%) and renal impairment (27%) at presentation.⁹⁴ Microscopic hematuria and proteinuria may occur in up to 35% of patients. The significance of these findings in terms of subsequent deterioration of renal function is unclear.⁹⁵ Amyloidosis (secondary type) is a rare complication. Amyloid deposits detected through abdominal subcutaneous fat aspiration are not invariably associated with a poor renal prognosis.⁹⁶

Osteoporosis

Osteopenia is seen in the early stages of AS.⁹⁷ In patients with this disease, osteoporotic deformities of the thoracic spine contribute significantly to abnormal posture, particularly fixed hyperkyphosis.⁹⁸ Radiographic damage to the cervical and lumbar spine, thoracic wedging, and disease activity are determinants of hyperkyphosis in AS.⁹⁹ An increased occiput-to-wall distance is associated with vertebral fractures. The prevalence of symptomatic osteoporotic spinal fractures is increased in AS.¹⁰⁰ Neurologic complications occur rather frequently, even after minor trauma.¹⁰¹ Proper assessment of bone density in the spine is difficult in the presence of syndesmophytes because they may give rise to falsely high values. The true fracture risk and complication rate in early and late disease and the relation to disease activity are not yet known. Currently, it is unclear whether any specific antiosteoporotic therapy to prevent spinal fractures is effective.

PHYSICAL FINDINGS

Spinal Mobility

To arrive at an early diagnosis, the physician must perform a thorough physical examination. On examination of the spine, there may be some limitation of motion of the lumbar spine as elicited by forward flexion, hyperextension, or lateral flexion. Early loss of the normal lumbar lordosis is often the first sign and is easily assessed on inspection.

The Schober test (or its modifications) is useful to detect any limitation of forward flexion of the lumbar spine, although it is typically normal in early disease. As the patient stands erect, one mark is placed with a pen on the skin overlying the fifth lumbar spinous process (usually at the level of the posterosuperior iliac spine or the “dimple of Venus,” and another mark is placed 10 cm above in the midline. The patient is then asked to bend forward maximally without bending the knees. In healthy people, the

distance between the two marks on the skin should increase as the skin stretches. If the distance between both marks does not reach 15 cm, this indicates reduced lumbar spine mobility. Lateral flexion may also be diminished, and spinal rotation may cause pain.

Chest Expansion

Mild to moderate reduction of chest expansion is often detectable in early stages of AS. Normal values are age and sex dependent, and there is considerable overlap between normal values and those obtained from AS patients. Reduction below 5 cm in young persons with an insidious onset of chronic, inflammatory low back pain strongly suggests AS. Chest expansion should be measured on maximal inspiration after forced maximal expiration at the level of the fourth intercostal spondyloarthritise in males and just below the breasts at the xiphisternal level in females.

Enthesitis

Examination of the ischial tuberosities, greater trochanters, spinous processes, costochondral and manubriosternal junctions, supraspinatus insertion, and iliac crests can determine the presence of enthesitis. Heel pain, especially when getting out of bed, is a characteristic manifestation of Achilles and plantar fasciitis enthesitis.

Sacroiliitis

Direct pressure over the SI joints may elicit pain, as may special testing maneuvers, although the latter lack specificity and sensitivity. These signs may also be negative in early disease or may become negative in late stages as inflammation is replaced by fibrosis or bony ankylosis.

Posture

Over the course of the disease, the patient may lose normal posture. Involvement of the cervical spine is manifested by pain and limitation of neck movement. A forward slope of the neck can be detected by having the patient stand against a wall and try to position his or her occiput against it.

After many years of progression in patients with severe disease, the entire spine may become increasingly stiff, with loss of normal posture from gradual loss of lumbar lordosis and the development of thoracic kyphosis.^{98,99} The abdomen becomes protuberant; breathing is primarily by diaphragmatic action. These typical deformities usually evolve after disease duration of 10 years or more.

LABORATORY TESTS

Generally, routine blood tests are not helpful. A normal erythrocyte sedimentation rate (ESR) or normal C-reactive protein (CRP) level does not exclude active disease. An elevated ESR or CRP is reported in up to 75% of patients, but it may not correlate with clinical disease activity.¹⁰² In an unselected patient population, an elevated ESR and CRP was present in 45% and 38%, respectively, of patients with spinal disease only, compared with 62% and 61%, respectively, of patients with peripheral arthritis with or

without inflammatory bowel disease. Neither ESR nor CRP is superior in assessing disease activity.¹⁰³ A mild normochromic anemia may be present in 15% of patients. Elevation of serum alkaline phosphatase (derived primarily from bone) is seen in some patients but is unrelated to disease activity or duration. Some elevation of serum IgA is frequent in AS. Its level correlates with acute-phase reactants. Active disease is associated with decreased lipid levels, particularly high-density lipoprotein cholesterol, resulting in a more atherogenic lipid profile.¹⁰⁴

IMAGING STUDIES

Conventional Radiography

The typical radiographic changes of AS are seen primarily in the axial skeleton, especially in the SI, discovertebral, apophyseal, costovertebral, and costotransverse joints. They evolve over many years, with the earliest, most consistent, and most characteristic findings seen in the SI joints. However, otherwise typical AS has been described in the absence of radiographic evidence of sacroiliitis.⁸ The radiographic findings of sacroiliitis are usually symmetric and consist of blurring of the subchondral bone plate, followed by erosions and sclerosis of the adjacent bone. The changes in the synovial portion of the joint (i.e., the lower two-thirds of the joint) result from inflammatory synovitis and osteitis of the adjacent subchondral bone.¹⁰⁵ The cartilage covering the iliac side of the joint is much thinner than that covering the sacral side. Therefore the erosions and subchondral sclerosis are typically seen first and tend to be more prominent on the iliac side.

In the upper one-third of the SI joint, where strong intra-articular ligaments hold the bones together, the inflammatory process may lead to similar radiographic abnormalities. Progression of the subchondral bone erosions can lead to pseudowidening of the SI joint space. Over time, gradual fibrosis, calcification, interosseous bridging, and ossification occur. Erosions become less obvious, but the subchondral sclerosis persists, becoming the most prominent radiographic feature.

Ultimately, usually after several years, there may be complete bony ankylosis of the SI joints, with resolution of bony sclerosis. It is practical to grade radiographic sacroiliitis according to the New York criteria (Table 75-8).

Bony erosions and osteitis (“whiskering”) at sites of osseous attachment of tendons and ligaments are frequently seen, particularly at the calcaneus, ischial tuberosities, iliac crest, femoral trochanters, supraspinatus insertion, and spinous processes of the vertebrae. In the early stages of the evolution of syndesmophytes, there is inflammation of the superficial layers of the annulus fibrosus, with subsequent reactive sclerosis and erosions of the adjacent corners of the

vertebral bodies. This combination of destructive osteitis and repair leads to “squaring” of the vertebral bodies. This squaring is associated with gradual ossification of the annulus fibrosus and eventual “bridging” between vertebrae by syndesmophytes.¹⁰⁶ There are often concomitant inflammatory changes, ankylosis in the apophyseal joints, and ossification of the adjacent ligaments. In a number of patients, this may ultimately result in a virtually complete fusion of the vertebral column (“bamboo spine”).

Hip involvement may lead to symmetric, concentric joint spondylarthritice narrowing, irregularity of the subchondral bone with subchondral sclerosis, osteophyte formation at the outer margin of the articular surface, and, ultimately, bony ankylosis of these joints.

Several validated scoring methods are available to quantify structural damage in AS: the Bath AS radiology index (BASRI), the Stoke AS spondylitis score (SASSS), and the modified SASSS.¹⁰⁷⁻¹⁰⁹ The BASRI includes scores for the cervical and lumbar spine, as well as the SI joints. A similar score for the hips is also available. The SASSS evaluates the lumbar spine only; the modified SASSS assesses the anterior, cervical, and lumbar spine. These scoring methods are most suited for use in clinical trials and observational studies.

Computed Tomography and Magnetic Resonance Imaging

The conventional plain pelvic radiograph is still the initial tool for the evaluation of SI joints in patients with inflammatory low back pain. This technique, however, lacks sensitivity in early sacroiliitis because it only detects structural abnormalities that are the consequence of inflammation. CT may detect bone abnormalities such as sclerosis and erosion sooner than plain radiography, but its use is limited by radiation exposure and it does not detect changes in soft tissues or bone marrow where early features of sacroiliitis develop. MRI sequences that are used in routine practice to image the SI joint can detect sacroiliitis in 50% of patients with preradiographic SpA.¹¹⁰ These sequences include fat-saturating techniques, such as short tau inversion recovery (STIR), that are very sensitive in the detection of bone marrow edema, which is a frequent finding in AS-related inflammation of the musculoskeletal system (Figure 75-2). The T1-weighted sequence allows detection of erosions and fat infiltration, which may occur early in disease and is associated with resolution of inflammation. Diagnostic MRI should include both sequences, while the role of contrast enhancement with gadolinium is still unclear due to its substantial cost and prolonged time for imaging, which patients may find difficult to endure.

Similarly, plain spinal radiographs only show abnormalities once disease is well established, and it plays a minor role in diagnostic or ongoing routine evaluation except to detect other causes of back pain, such as spinal fractures. Characteristic abnormalities include square vertebrae, shiny corners (the Romanus lesion), spondylodiscitis (the Anderson lesion), and syndesmophytes with partial and complete fusion. Spinal inflammation can only be visualized by MRI, where it is typically seen as bone marrow edema in the vertebrae at both anterior and posterior vertebral corners as well as around the intervertebral disk. Lateral and posterior

Table 75-8 Grading of Sacroiliitis: New York Criteria

Grade 0, normal
Grade 1, suspicious
Grade 2, minimal sacroiliitis
Grade 3, moderate sacroiliitis
Grade 4, ankylosis

Figure 75-2 T1-weighted (*left*) and short-tau inversion recovery sequence magnetic resonance (*right*) images of 23-year-old male with inflammatory back pain and equivocal pelvic radiograph demonstrating the following features: *A*, Bone marrow edema in left iliac and sacral bones. *B*, Capsular inflammation. *C*, Joint space inflammation. *D*, Diffuse erosion of left iliac bone with widening of joint space. *E*, Fat infiltration in right sacrum and ilium.

elements such as the costovertebral and costotransverse joints, facet joints, pedicles, and spinal ligaments can also show inflammatory lesions.¹¹¹ MRI and ultrasonography can be very useful to assess enthesitic problems such as Achilles tendinitis and heel pain.

Quantification of spinal inflammation using MRI is highly sensitive to change and is increasingly recognized as an essential component of clinical trials. MRI scores for inflammation correlate with CRP but not with symptoms. Increasing evidence supports an association between MRI inflammation and the future development of structural changes on radiography.^{112,113}

DIAGNOSIS

Clinical manifestations of AS usually begin in late adolescence or early adulthood; only rarely do they begin after age 40 years.⁸ The diagnosis of AS at an early stage of disease depends primarily on a careful history and physical examination. Two features of the history are critical: (1) the presence of inflammatory low back pain and stiffness and (2) a positive family history for AS.

Low back pain is common in the general population and is frequently due to noninflammatory, nonspecific mechanical causes. However, the low back pain in AS has typical “inflammatory” features (see Table 75-6). A history of inflammatory low back pain can be used as a diagnostic tool. A reassessment of the clinical history for diagnostic purposes among young to middle-aged adults (younger than 50 years) with chronic back pain and an established diagnosis of either AS or mechanical back pain revealed a sensitivity of 37% (95% CI, 28 to 46), a specificity of 84% (95% CI, 76 to 90), a positive likelihood ratio of 2.3 (95% CI, 1.4 to 3.7), and a post-test probability of AS of 11% (given a pretest probability of 5%) if two of the four parameters listed in Table 75-9 were present. If three or four of these items were present, the sensitivity was 34% (95% CI, 25 to 43), the specificity was 97% (95% CI, 92 to 99), the positive likelihood ratio was 12.4 (95% CI, 4.0 to 40), and the post-test probability of AS was 39%.⁸¹ Because the prevalence of AS in many white populations is as low as approximately

0.1% to 0.3%, applying the clinical history as a test for the disease in such low-probability settings provides rather low post-test probability values. However, a positive family history increases the pretest probability of AS from 0.1% for a person belonging to the general population to about 10% for any first-degree relative of an AS proband.⁸ The probability of having AS for a first-degree relative with a positive family history of AS increases from 10% to nearly 50% if this relative has inflammatory low back pain. In contrast, the likelihood of having AS increases from 0.1% to only 1% for a person who has inflammatory back pain (without any other inflammatory indications listed in Table 75-9) but has a negative family history for AS.

A definite diagnosis of AS is usually established by radiographic evidence of bilateral sacroiliitis. The plain anteroposterior view of the pelvis is usually adequate for diagnostic purposes. There is, however, considerable intraobserver and interobserver variation in the radiographic diagnosis of sacroiliitis for both conventional pelvic films and CT of the SI joints. Training in reading these films has limited value. Improvement in sensitivity tends to be associated with a decrease in specificity.¹¹⁷

In most adult patients, AS can be diagnosed clinically without the *HLA-B27* test. This assessment has no additional value in established disease or as a pure screening tool.¹¹⁸ However, in young patients with inflammatory chronic back pain, a positive *HLA-B27* test increases the likelihood of having AS, particularly if imaging of the SI

Table 75-9 Proposed Criteria for Inflammatory Back Pain in Young to Middle-aged Adults* with Chronic Back Pain

Morning stiffness of at least 30 min duration
Improvement of back pain with exercise but not with rest
Awakening because of back pain during second half of night only
Alternating buttock pain

*Younger than 50 yr.

From Rudwaleit M, Metter A, Listing J, et al: Inflammatory back pain in ankylosing spondylitis: a reassessment of the clinical history for application as classification and diagnostic criteria, *Arthritis Rheum* 65:569–578, 2006.

joints does not provide conclusive results. Usually, however, the contribution of *HLA-B27* typing to purely clinical factors in diagnosing axial manifestations of AS among patients with inflammatory back pain of short duration is rather limited, whereas MRI may help in classifying patients as having spondyloarthritis or nonspondyloarthritis.¹¹⁹

Physicians are reluctant to make the diagnosis of AS when radiographic evidence of sacroiliitis is not present. Relatives of AS patients in particular may have signs and symptoms of AS including inflammatory back pain but sometimes do not show radiographic sacroiliitis even after lengthy follow-up. Radiographic sacroiliitis is frequent in AS but is by no means an early or obligate manifestation of the disease. In patients with a clinical diagnosis of possible AS, radiographic sacroiliitis may never become manifest or only after appropriate follow-up. Therefore diagnosing this type of disease, which fits entirely into the concept of axial spondyloarthritis, early, before (conventional) radiographic evidence of sacroiliitis is manifest, constitutes a challenge to the clinician. This is especially true as more effective treatments become increasingly available. In this context, the term (nonradiographic) axial spondyloarthritis is often used. An approach based on pretest probabilities and likelihood ratios has been proposed to diagnose early disease with predominantly axial manifestations before convincing evidence of radiographic sacroiliitis is present.⁸¹ The majority of patients diagnosed clinically with preradiographic axial spondyloarthritis have MRI evidence of spondyloarthritis,¹²⁰ and the severity of bone edema on MRI has been shown to predict the development of radiographic sacroiliitis on follow-up.¹²¹ Consequently, MRI is now an acceptable imaging criterion for the diagnosis of spondyloarthritis and is especially useful when the history points to inflammatory back pain, the pelvic radiograph is normal or equivocal, and the patient is positive for B27.

AS rarely develops after age 40; however, late-onset AS does occur. In this case, there may be little or no clinical involvement of the axial skeleton initially, but patients may show moderate oligoarthritis with low cell counts in the synovial fluid and pitting edema of the lower limbs.¹²²

At the other end of the age scale, juvenile-onset AS is not uncommon among young patients with spondyloarthritis. Such patients tend to have enthesitis and peripheral arthritis, which may be severe and disabling.

ANKYLOSING SPONDYLITIS IN MALES AND FEMALES

Clinically, AS is more common in males, with a reported male-to-female ratio of about 2:1 to 3:1. However, extrapolation of studies employing the genetic marker *HLA-B27* suggests that, on the basis of radiographs of the SI joints, prevalence rates are about equal in both sexes.⁸

Disease expression is thought to be different in males and females. A case-control study comparing 35 female patients with 70 male patients as controls showed no differences in spinal symptoms, chest expansion, peripheral arthritis, extra-articular manifestations, or functional outcome. The males with AS more often had radiographic spinal changes and hip joint involvement than their female counterparts. There is still some controversy, but overall, there are no

significant clinical or radiographic differences between women and men with AS. However, on average, the disease seems to be more severe in men.^{123,124}

Fertility among female patients with AS is normal.¹²⁵ Most patients (50% to 60%) do not experience major changes in disease activity during pregnancy, but an increase in morning stiffness and low back pain, particularly at night, may occur at about the 20th week of gestation and last for a few days to weeks.¹²⁶ In about 50% of patients, an exacerbation of symptoms is seen within the first half year after delivery. Sacroiliitis including complete ankylosis of the SI joints does not constitute a contraindication for vaginal delivery. Epidural anesthesia is usually possible because most patients have a rather short duration of disease and do not have extensive spinal syndesmophytes. The fetal outcome is not impaired in patients with AS. Every pregnancy in patients with this disease should be considered potential high risk, however, and such pregnancies require close collaboration between rheumatologists and obstetricians.

An uncontrolled study among 612 AS patients (mean age, 50.8 years; 71.6% males) reported a substantial impact on sexual relationships (response rate, 38%). Poor function, depression, disease activity, unemployment, and poor self-efficacy were independently associated with greater impact on patients' sexual relationships.¹²⁷

OUTCOME

The course of AS is highly variable, characterized by spontaneous remissions and exacerbations. Its prognosis has generally been considered rather favorable. The disease may run a relatively mild or self-limited course. However, the disease may also remain active over many years. Life expectancy is somewhat reduced, particularly after 10 years of disease.¹²⁸ A study from Finland indicates that the risk of dying for patients with AS is increased by 50% compared with controls matched for age and gender. Causes of death include complications of the disease such as amyloidosis and spinal fractures, as well as cardiovascular, gastrointestinal, and renal disease.¹²⁹ There is no convincing evidence that the natural history of the disease has essentially changed over the past few decades.^{130,131} No differences exist between familial and sporadic AS in terms of age at onset, age at diagnosis, or prevalence of peripheral arthritis and acute anterior uveitis.¹³²

Functional limitations increase with disease duration. Although structural damage seen on radiographs is clearly associated with physical function and spinal mobility at the group level, individual patients with normal radiographs might exhibit a major reduction in spinal mobility, whereas those with severe radiographic abnormalities might function quite well in everyday tasks.¹³³

Recent data show that the functional prognosis of AS is less favorable than was previously thought. Withdrawal from work in those with paid jobs varies from 10% after 20 years of disease duration to 30% after 10 years, depending on the characteristics of the patients included and the social security system considered.¹³⁴⁻¹³⁷ The age- and sex-adjusted withdrawal rate from labor-force participation was 3.1 times higher among Dutch patients compared with the general population.¹³⁷ Older age at disease onset, manual work, lower educational level, and coping strategies characterized

by the limitation and pacing of activities were associated with a higher risk for work disability.¹³⁵⁻¹³⁷ Vocational counseling, job training, easy access to the workplace, and support of colleagues and management may reduce the probability of withdrawal from work.^{134,138} Sick leave in those with paid jobs was linked to disease activity and presence of extraspinous disease manifestations.^{134,137,139} Patients with peripheral joint involvement are more likely to take sick leave than are AS patients with axial manifestations only.

Overall, the first 10 years of disease are particularly important with respect to subsequent outcome. Most of the loss of function among patients with AS occurs within this period and is associated with the presence of peripheral arthritis, spinal radiographic changes, and development of a so-called bamboo spine.¹⁴⁰ In a retrospective study of patients with spondyloarthropathies including AS, of at least 10 years' duration, seven variables were associated with disease severity if these factors occurred within the first 2 years of follow-up. These factors, expressed as an odds ratio together with its 95% CI, are as follows: arthritis of hip joints (22.9; 4.4 to 118), ESR more than 30 mm/hr (7; 4.8 to 9.5), poor efficacy of nonsteroidal anti-inflammatory drugs (NSAIDs) (8.3; 2.6 to 27.1), limitation of lumbar spine (7; 2 to 25), sausage-like digits (8.5; 1.5 to 9.0), oligoarthritis (4.3; 1.4 to 13.1), and onset before age 16 years (3.5; 1.1 to 12.8).¹⁴¹ Although radiographic progression is highly variable among patients, radiographic evidence of spinal involvement, especially the presence of syndesmophytes, appears to be the primary factor that independently predicts further radiographic progression.¹⁴² The long-term results of total hip replacement in AS are satisfactory. The outcome of 138 total hip replacements and 12 revisions was good or very good in 86%, and 63% of patients had no pain. Mobility was good or very good in 44%. The mean follow-up was 7.5 years (range, 1 to 34 years). Altogether, 69% of the male hip recipients younger than 60 years were at work at the time of the survey.¹⁴³

ASSESSMENT AND MONITORING

Signs and symptoms such as spinal pain and limitation of motion might be due to current disease activity or to damage. A plethora of tools is available to assess these dimensions. For example, there are many ways to measure limitation of motion of the lumbar spine. New instruments have been developed to assess various aspects of the disease including the Bath and Edmonton AS metrology indices, Bath AS global index, BASRI, Bath AS disease activity index, and Dougados functional index.¹⁴⁴⁻¹⁴⁹ However, standardization and validation of many of these instruments are lacking or incomplete. An international Assessment in Ankylosing Spondylitis (ASAS) working group was formed with the aim of selecting, proposing, and testing core sets of measures for different settings.¹⁵⁰ It was thought that a certain set of variables should be targeted to a specific task. For example, when assessing the efficacy of physical therapy, it would not be realistic to include measures of radiographic changes of the spine. Clearly, the set of measures for a drug's disease-modifying capabilities will differ from a set that measures analgesic effectiveness only. Four settings have been defined: disease-controlling

Table 75-10 World Health Organization–International League of Associations for Rheumatology Core Sets for Ankylosing Spondylitis

Domain	Instrument
Function	BASFI or Functional Index Dougados
Pain	VAS: last week, spine pain at night due to AS
Spinal mobility	VAS: last week, spine pain due to AS Chest expansion and modified Schober and occiput to wall distance (lateral spinal flexion or BASMI)
Patient global assessment	VAS: last week
Stiffness	Duration of morning spine stiffness, last week
Peripheral joints and entheses	Number of swollen joints (44 joint count); validated enthesitis index
Acute-phase reactants	Erythrocyte sedimentation rate
Spine radiographs	Lateral view of lumbar spine and lateral view of cervical spine
Hip radiographs	Pelvic radiograph including sacroiliac joints and hips
Fatigue	VAS on fatigue from BASDAI

Disease-controlling antirheumatic therapy domains: 1-10; symptom-modifying antirheumatic drug domains: 1-5, 10; physical therapy domains: 1-5, 10; clinical record-keeping domains: 1-7.

antirheumatic therapy; symptom-modifying antirheumatic drugs such as NSAIDs; physical therapy; and clinical record keeping in daily practice (Table 75-10).¹⁵⁰ Also, criteria to assess the response of individual patients have been developed and validated. These ASAS-20 improvement criteria are frequently used in clinical trials.¹⁵¹ In addition, more stringent improvement criteria—ASAS-40 and ASAS-5/6—have been proposed,¹⁵² as well as criteria to define partial remission. The three sets of improvement criteria and the partial remission criteria are presented in Table 75-11.^{151,152} The recently developed Ankylosing Spondylitis Disease Activity Score (ASDAS) enables defining disease activity states and demonstrating improvement by applying cutoff values.¹⁵³

A needs-based quality-of-life instrument specific for AS has been developed. It is well accepted and easy to perform and, in terms of assessing the impact of interventions, has shown good scaling and psychometric properties and sensitivity to change.^{154,155}

MANAGEMENT

A systematic review of the literature on the management of AS culminated in a series of treatment propositions developed by ASAS/European League Against Rheumatism (EULAR) that emphasize the key evidence-based components of disease management (Table 75-12; Figure 75-3).^{156,157} For most patients, AS is a relatively mild disease with a good functional prognosis. Most do not experience significant extraskeletal manifestations except for acute anterior

uveitis, which occurs in about 30% of patients. Usually, this eye disease can be well managed with eye drops containing corticosteroids to reduce inflammation and with pupil-dilating, atropine-like agents to prevent or diminish synechiae. At the outset, patients should be warned that acute

anterior uveitis may occur at any time during the course of the disease.

The treatment objectives in AS are to relieve pain, stiffness, and fatigue and to maintain good posture and good physical and psychosocial functioning.¹⁵⁸ No drug is currently available that significantly influences the course of spinal disease and retards the process of ossification in particular. Similarly, evidence is lacking that any of the conventional disease-modifying antirheumatic drugs including sulfasalazine and methotrexate alter or inhibit the inflammation seen in the spine and entheses in AS.

A full explanation of the disease, its course, possible complications (e.g., acute anterior uveitis), and its prognosis is essential to achieve compliance by the patient. Self-help groups provide important information and social support. In addition, patient organizations often provide access to hydrotherapy and group physiotherapy. Exercises are the mainstay of treatment. Preferably, they should be started after a hot shower or a hot bath. Swimming and extension-promoting exercises or sporting activities such as volleyball or cross-country skiing are appropriate. These activities counteract the kyphotic effects of pain and fatigue on posture and reduce stiffness. Patients should avoid vigorous or contact sports if the spine has become fused or osteoporotic because such a spine is susceptible to fracture.

Appliances such as driving mirrors may improve comfort and safety, especially if there is considerable involvement of the cervical spine. In that case, appropriate neck support is also required to reduce the risk of fracturing the vulnerable osteoporotic cervical spine as a consequence of traffic accidents. For the same reason, automobile air bags are strongly recommended.

Physiotherapy

Evidence indicates that physiotherapy in the form of exercises is effective, at least in the short term (up to 1 year). In a randomized, controlled trial, a program of supervised physiotherapy in groups was superior to individualized programs in improving thoracolumbar mobility and fitness. The program, which consisted of hydrotherapy, exercises, and sporting activities twice weekly for 3 hours per session, resulted in improved overall health and less stiffness, as reported by the patient.¹⁵⁹ An intensive 3-week spondyloarthritis exercise therapy program resulted in marked improvement in both subjective and objective assessments that lasted for up to 9 months. Health resource utilization, in particular NSAID use and sick leave, was significantly reduced during this 9-month follow-up period. The clinical benefits of such treatments can be achieved at acceptable costs.^{160,161} A Cochrane review concluded that a home exercise program is better than no intervention, supervised group physiotherapy is better than home exercises, and that combined inpatient spa-exercise therapy followed by supervised outpatient weekly group physiotherapy is better than weekly group physiotherapy alone (level A evidence) (Table 75-13).¹⁶² The tendency toward positive effects of physiotherapy in the management of AS calls for further research in this field. New trials should also address other physiotherapy interventions commonly used in clinical practice. Moreover, the impact on physical functioning of physiotherapy in patients who respond well to biologics needs

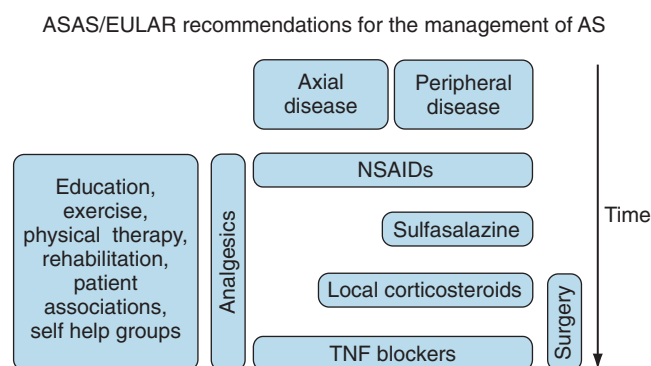

Figure 75-3 Recommended management of ankylosing spondylitis (AS), based on clinical expertise and research evidence. The disease progression with time moves vertically from top to bottom. Table 75-12 First Update of the ASAS/EULAR Recommendations for the Management of Ankylosing Spondylitis (AS)

<p>The overarching principles of the management of patients with AS are:</p> <p>AS is a potentially severe disease with diverse manifestations, usually requiring multidisciplinary treatment coordinated by the rheumatologist</p> <p>The primary goal of treating the patient with AS is to maximize long term health-related quality of life through control of symptoms and inflammation, prevention of progressive structural damage, preservation/normalization of function, and social participation</p> <p>Treatment of AS should aim at the best care and must be based on a shared decision between the patient and the rheumatologist</p> <p>The optimal management of patients with AS requires a combination of nonpharmacologic and pharmacologic treatment modalities</p>
1. General Treatment
<p>The treatment of patients with AS should be tailored according to:</p> <p>The current manifestations of the disease (axial, peripheral, enthesal, extra-articular symptoms and signs)</p> <p>The level of current symptoms, clinical findings, and prognostic indicators</p> <p>The general clinical status (age, gender, comorbidity, concomitant medications, psychosocial factors)</p>
2. Disease Monitoring
<p>The disease monitoring of patients with AS should include:</p> <p>Patient history (e.g., questionnaires)</p> <p>Clinical parameters</p> <p>Laboratory tests</p> <p>Imaging</p> <p>All according to the clinical presentation as well as the ASAS core set</p> <p>The frequency of monitoring should be decided on an individual basis depending on:</p> <p>Course of symptoms</p> <p>Severity</p> <p>Treatment</p>
3. Nonpharmacologic Treatment
<p>The cornerstone of nonpharmacologic treatment of patients with AS is patient education and regular exercise</p> <p>Home exercises are effective. Physical therapy with supervised exercises, land or water based, individually or in a group, should be preferred as these are more effective than home exercises</p> <p>Patient associations and self-help groups may be useful</p>
4. Extra-articular Manifestations and Comorbidities
<p>The frequently observed extra-articular manifestations (e.g., psoriasis, uveitis, and inflammatory bowel disease) should be managed in collaboration with the respective specialists</p> <p>Rheumatologists should be aware of the increased risk of cardiovascular disease and osteoporosis</p>
5. Nonsteroidal Anti-inflammatory Drugs (NSAIDs)
<p>NSAIDs, including coxibs, are recommended as first-line drug treatment for AS patients with pain and stiffness</p> <p>Continuous treatment with NSAIDs is preferred for patients with persistently active, symptomatic disease</p> <p>Cardiovascular, gastrointestinal, and renal risks should be taken into account when prescribing NSAIDs</p>
6. Analgesics
<p>Analgesics, such as paracetamol and opioid (like) drugs, might be considered for residual pain after previously recommended treatments have failed, are contraindicated, and/or are poorly tolerated</p>
7. Glucocorticoids
<p>Corticosteroid injections directed to the local site of musculoskeletal inflammation may be considered</p> <p>The use of systemic glucocorticoids for axial disease is not supported by evidence</p>
8. Disease-modifying Antirheumatic Drugs (DMARDs)
<p>There is no evidence for the efficacy of DMARDs, including sulfasalazine and methotrexate, for the treatment of axial disease</p> <p>Sulfasalazine may be considered in patients with peripheral arthritis</p>
9. Anti-Tumor Necrosis Factor (TNF) Therapy
<p>Anti-TNF therapy should be given to patients with persistently high disease activity despite conventional treatments according to the ASAS recommendations</p> <p>There is no evidence to support the obligatory use of DMARDs before or concomitant with anti-TNF therapy in patients with axial disease</p> <p>There is no evidence to support a difference in efficacy of the various TNF inhibitors on the axial and articular/enthesal disease manifestations, but in the presence of inflammatory bowel disease a difference in gastrointestinal efficacy needs to be taken into account</p> <p>Switching to a second TNF blocker might be beneficial, especially in patients with loss of response</p> <p>There is no evidence to support the use of biologic agents other than TNF inhibitors in AS</p>
10. Surgery
<p>Total hip arthroplasty should be considered in patients with refractory pain or disability and radiographic evidence of structural damage, independent of age</p> <p>Spinal corrective osteotomy may be considered in patients with severe disabling deformity</p> <p>In patients with AS and an acute vertebral fracture, a spinal surgeon should be consulted</p>
11. Changes in the Disease Course
<p>If a significant change in the course of the disease occurs, causes other than inflammation, such as a spinal fracture, should be considered and appropriate evaluation, including imaging, should be performed</p>

ASAS, Assessment in Ankylosing Spondylitis; EULAR, European League Against Rheumatism.

From van der Heijde D, Sieper J, Maksymowych WP, et al: 2010 update of the international ASAS recommendations for the use of anti-TNF agents in patients with axial spondyloarthritis, *Ann Rheum Dis* 70:905–908, 2010.

Table 75-13 Cochrane Review of
Physiotherapeutic Interventions and
Spondyloarthritis Therapy for Patients with
Ankylosing Spondylitis: Conclusions

Home exercise programs are better than no intervention
Supervised group physiotherapy is better than home exercise
Combined inpatient spondyloarthritis and exercise therapy
followed by supervised outpatient weekly group physiotherapy
is better than weekly group physiotherapy alone

to be assessed. Although these patients may experience relief of symptoms, the formation and progression of syndesmophytes may not be influenced by TNF-blocking agents.⁶⁸ This reinforces the ongoing need for supplementary therapeutic modalities such as physiotherapy in some patients with AS.

Lying prone for 15 to 30 minutes once or several times a day is useful to reverse the tendency toward kyphosis, which is aggravated by pain and fatigue, as well as flexion contractures of the hip joints. Patients should sleep fully supine on a firm mattress with only a small neck-support pillow.

Medication

Nonsteroidal Anti-inflammatory Drugs

The efficacy and effectiveness of NSAID therapy for the alleviation of symptoms have been well established (level A evidence). When given for prolonged periods of up to a year, there may be improvement in spinal mobility and acute-phase reactants.¹⁶³ Many NSAIDs are effective in patients with AS, and no NSAID has documented superiority in terms of efficacy. Selective cyclooxygenase-2 (COX-2) inhibitors have similar efficacy to conventional NSAIDs (level A evidence).¹⁶⁴ A nonselective NSAID is appropriate for most patients with AS, who tend to be relatively young and without comorbidity. A COX-2-selective agent may be used in the presence of risk factors for peptic ulceration, although both categories of NSAIDs may exacerbate inflammatory bowel disease. Once-daily drug regimens may improve patient compliance. Up to 2 weeks may be required to demonstrate maximal symptomatic benefit from an NSAID. If symptomatic relief is inadequate, a switch to another NSAID may be worthwhile; failure of two NSAIDs should prompt an exploration of other management strategies.

Given the gastrointestinal and cardiovascular risks of taking NSAIDs or coxibs, one must address whether this treatment should be on a daily or an “on-demand” basis. A 2-year randomized, prospective, controlled trial in AS patients compared the efficacy of continuous NSAID therapy with that of intermittent on-demand use. The results suggest that continuous therapy retards radiographic disease progression.¹⁶⁵ This study is in line with an older study that also suggested a possible disease-controlling effect of continuous therapy.¹⁶⁶ However, these findings require confirmation by studies less liable to bias.¹⁶⁷

Second-Line Drugs

Borrowing well-established concepts in the treatment of RA, disease-controlling therapy for AS has been defined as an agent that decreases inflammatory manifestations of disease, sustains or improves function, and prevents or decreases the rate of progression of structural damage. Although most of the second-line agents developed primarily for RA have been studied in AS, none can be considered disease controlling in AS. The greatest amount of data is available for sulfasalazine, which was first proposed as a therapy for AS in 1984, based on the common association between inflammatory bowel disease and spondyloarthritis, the description of inflammatory lesions in the ileum of patients with spondyloarthritis, and its success in the treatment of intestinal inflammation.¹⁶⁸ A total of 11 double-blind, placebo-controlled trials have been published, as well as two meta-analyses. The results of the two largest trials were consistent, demonstrating no significant benefit for sulfasalazine in AS, although subgroup analysis showed that patients with (peripheral) polyarthritis—mostly those with psoriatic arthritis, but also AS patients with peripheral joint involvement—had a significant but modest response.^{169,170} An important limitation in most of these studies was the long disease duration (>10 years) of recruited patients, and it has been suggested that early disease may be more responsive to therapy. However, a 24-week placebo-controlled trial that recruited 230 patients meeting European Spondyloarthropathy Study Group (ESSG) criteria for spondyloarthritis and with symptom duration of less than 5 years confirmed that sulfasalazine was ineffective.¹⁷¹ The most recent meta-analysis, based on 11 trials, concluded that this agent has a significant impact only on the ESR and the severity of spinal stiffness (level A evidence).¹⁷² The primary indication for the use of sulfasalazine in routine practice is a patient who has concomitant peripheral arthritis and has had an inadequate response to NSAIDs and physical modalities.

The evaluation of methotrexate in AS has been limited to case reports and open analyses, mostly reported in abstract form. These studies have included limited numbers of patients for periods of 6 months to 3 years, at doses from 7.5 to 15 mg weekly. The results have been mixed, with some benefit noted in patients with concomitant peripheral arthritis. Two small placebo-controlled trials assessed methotrexate in doses of 10 and 7.5 mg weekly for 24 weeks, with contradictory findings.^{173,174} A meta-analysis concluded that there was no evidence of efficacy and that higher-quality trials, larger sample sizes, longer durations of treatment, and higher dosages of methotrexate were necessary before any definitive conclusions could be drawn (level B evidence).¹⁷⁵

Corticosteroids may be effective for local intra-articular treatment in AS including the SI joints, if given under fluoroscopic guidance (level B evidence). Systemic steroids are of unproven benefit and are thought to be less effective than in RA (level C evidence). Leflunomide has been studied in AS, and although an open-label study suggested a benefit in patients with peripheral arthritis, a small placebo-controlled study reported no benefit (level B evidence).^{176,177} A controlled dose-response (60 mg vs. 10 mg) evaluation of a bisphosphonate, pamidronate, given intravenously on

a monthly basis for 6 months showed evidence of symptomatic efficacy, primarily in patients with only axial disease (level B evidence).¹⁷⁸ However, this finding needs to be confirmed.

Thalidomide has been used in two open-label studies in AS because it enhances the degradation of TNF messenger RNA. In a Chinese study, improvement was reported in 80% of patients, with deterioration 3 months after treatment discontinuation. Frequent side effects are drowsiness, constipation, and dizziness (level B evidence).¹⁷⁹

Biologic Therapies

A milestone in the treatment of AS is the development of anti-TNF therapies. The rationale is based on the finding of TNF expression in SI joint biopsies of AS patients, the observation that overexpression of TNF leads to sacroiliitis in animal models, and earlier clinical trial data demonstrating the efficacy of one anti-TNF agent, infliximab, in Crohn's disease. Four anti-TNF agents are of proven benefit in AS according to pivotal phase III trials (level A evidence): infliximab, etanercept, adalimumab, and golimumab. Infliximab is an IgG1 chimeric monoclonal antibody with the Fab portion derived from the mouse. It is given in a dose of 3 to 5 mg/kg every 6 to 8 weeks after loading at 0, 2, and 6 weeks. Etanercept is a recombinant 75-kD TNF receptor IgG1 fusion protein that is self-administered by subcutaneous injection either once (50 mg) or twice (25 mg) weekly. Adalimumab and golimumab are human monoclonal antibodies that are self-administered by subcutaneous injection on alternate weeks (40 mg) or monthly (50 mg), respectively. None require concomitant therapy with methotrexate.

All these agents demonstrate ASAS-20 response rates of 55% to 60% and ASAS-40 response rates of 45% to 50% in phase III trials.¹⁸⁰⁻¹⁸⁴ Even higher response rates have been observed in patients with preradiographic axial spondyloarthritis and short disease duration who received adalimumab or infliximab in placebo-controlled trials.^{185,186} Improvement is evident by 2 to 4 weeks and is sustained as long as the patient remains on treatment; virtually all patients relapse by 4 months after discontinuation of treatment.¹⁸³ Significant improvement is also observed in function, spinal mobility, peripheral synovitis, enthesitis score, and quality of life. Sick leave and work disability are reduced. The number of patients who must be treated to achieve one patient who experiences at least 50% improvement in disease activity is just two (95% CI, 1 to 6). Objective parameters of disease activity that show improvement include acute-phase reactants, synovial histopathology, and MRI features of inflammation in the spine and SI joints.¹⁸⁷ As of now, no evidence indicates that these agents are disease controlling with respect to the prevention of structural damage on plain radiography.⁶⁸ Response to treatment appears to be increased in those with high disease activity and worse in those with a long disease duration, impaired function, and no discernible evidence of inflammation on MRI.¹⁸⁸ However, patients with complete spinal ankylosis may benefit from these treatments.¹⁸² Adverse events in AS patients are no different from those reported in RA, and infusion reactions in patients receiving infliximab have

been no more frequent than in RA patients on concomitant methotrexate. All anti-TNF agents are effective for psoriasis, and the monoclonal anti-TNF antibodies, infliximab and adalimumab, also have demonstrated efficacy in both uveitis and colitis. Patients who fail to respond to one anti-TNF agent may respond to an alternative anti-TNF agent.

Recommendations for the use of anti-TNF therapies have been developed (Table 75-14).¹⁸⁹⁻¹⁹¹ These new therapeutic modalities identify important clinical questions to be answered by further research. All the anti-TNF agents examined to date have symptom-modifying properties, but their long-term safety and disease-controlling effects in terms of preventing structural damage have yet to be demonstrated.

Surgery

Involvement of the hip joint may cause serious disability. Ectopic bone formation may occur, but the outcome of total hip replacement is generally favorable.¹⁴³

Vertebral osteotomy may be required in selected cases to correct marked flexion deformity when forward vision is severely impaired. Diaphragmatic herniation may result from the procedure.

SUMMARY

Although understanding of AS genetics has improved greatly, knowledge about its cause and pathogenesis is far from complete. Much has been accomplished in terms of classification and assessment of the disease. Treatment with biologics such as anti-TNF is effective, but such therapy has not yet been shown to inhibit radiographic progression of spinal syndesmophytes. The challenge now is to determine how to predict and improve outcomes at the level of individual patients, in particular for those patients who will develop important structural changes and functional decline.

Future Directions

The long interval (on average) between the first symptoms of AS and the clinical diagnosis must be shortened.

Research into factors that accurately predict final outcome at the time of diagnosis is essential.

Study of which factors predict response to biologic therapy for individual AS patients is highly desirable. In addition, the long-term effects of treatment with biologics are not yet fully known.

Evidence of the effectiveness of preventing damage in terms of the development of syndesmophytes is still contradictory. It is largely unknown what triggers the process of ankylosing.

A few studies suggest that continuous (versus intermittent) use of NSAIDs or coxibs may slow the progression of axial radiographic manifestations of AS. These findings, however, are controversial. Therefore further studies on this issue are required.

Table 75-14 2010 Update of Recommendations for the Use of Anti-Tumor Necrosis Factor (TNF) Agents in Patients with Axial Spondyloarthritis (SpA)

Recommendation	
Patient Selection	
Diagnosis	Patients fulfilling modified New York Criteria for definitive AS* or the ASAS criteria for axial SpA
Active disease	Active disease for ≥ 4 wk BASDAI ≥ 4 (0-10) [†] and a positive expert opinion [‡]
Treatment failure	All patients should have had adequate therapeutic trials of at least two NSAIDs. An adequate therapeutic trial is defined as at least two NSAIDs over a 4-wk period in total at maximum recommended or tolerated anti-inflammatory dose unless contraindicated Patients with predominantly axial manifestations do not have to take DMARDs before anti-TNF treatment can be started Patients with symptomatic peripheral arthritis should have an insufficient response to at least one local steroid injection if appropriate and should normally have had an adequate therapeutic trial of a DMARD, preferably sulfasalazine Patients with symptomatic enthesitis must have failed appropriate local treatment
Assessment of Disease	
ASAS Core Set of Daily Practice	
Physical function (BASFI or Dougados functional index)	
Pain (VAS for spine at night from AS in the past week and VAS for spine from AS in the past week)	
Spinal mobility (chest expansion, modified Schober and occiput to wall distance, and lateral lumbar flexion)	
Patient's global assessment (VAS for the past week)	
Stiffness (duration of morning spine stiffness in the past week)	
Peripheral joints and entheses (number of swollen joints [44 total], enthesitis score such as developed in Maastricht, Berlin, or San Francisco)	
Acute-phase reactants (erythrocyte sedimentation rate or C-reactive protein)	
Fatigue (VAS)	
BASDAI	
VAS for overall level of fatigue or tiredness in the past week	
VAS for overall level of AS neck, back, or hip pain in the past week	
VAS for overall level of pain or swelling in joints other than neck, back, or hips in the past week	
VAS for overall discomfort from any areas tender to touch or pressure in the past week	
VAS for overall level of morning stiffness from time of awakening in the past week	
Duration and intensity (VAS) of morning stiffness from time of awakening (up to 120 min)	
Assessment of Response	
Responder criteria	BASDAI: 50% relative change or absolute change of 2 (on 0-10 scale) <i>and</i> expert opinion in favor of continuation
Time of evaluation	After at least 12 wk

*Modified New York criteria (van der Linden et al, 1984): radiologic criterion (sacroiliitis, grade \geq II bilaterally or grade III to IV unilaterally) and at least two out of three clinical criteria (low back pain and stiffness for more than 3 mo that improves with exercise but is not relieved by rest; limitation of motion of the lumbar spine in both the sagittal and frontal planes; limitation of chest expansion relative to normal values correlated for age and sex).

[†]BASDAI assessed on a 0-10 VAS or NRS.

[‡]The expert is a doctor, usually a rheumatologist, with expertise in inflammatory back pain and the use of biologic agents. Experts should be locally defined. An expert opinion should consider clinical features (history and examination) as well as either serum acute-phase reactant levels or imaging results, such as radiographs demonstration rapid progression or magnetic resonance imaging scans indicating inflammation.

ASAS core set for daily practice: physical function (BASFI); pain (VAS/NRS, last week, spine at night, due to AS and VAS/NRS, last week, spine due to AS); spinal mobility (chest expansion, cervical rotation, occiput-to-wall distance, modified Schober, and lateral lumbar flexion or BASMI); patient's global assessment (VAS/NRS, last week); stiffness (duration of morning stiffness, spine, VAS/NRS, last week); peripheral joints and entheses (number of swollen joints [44 joints count], enthesitis score such as developed in Maastricht, Berlin, or San Francisco); acute-phase reactants (preferably C-reactive protein); fatigue (VAS/NRS).

AS, ankylosing spondylitis; ASAS, Assessment in SpondyloArthritis international Society; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; BASFI, Bath Ankylosing Spondylitis Functional Index; BASMI, Bath Ankylosing Spondylitis Metrology Index; DMARD, disease-modifying antirheumatic drug; NRS, numeric rate scale; NSAIDs, nonsteroidal anti-inflammatory drugs; VAS, visual analogue scale.

KEY POINTS

Reactive arthritis is a form of spondyloarthritis triggered by particular infections.

Undifferentiated spondyloarthritis can have both peripheral and axial features.

Undifferentiated spondyloarthritis is a provisional diagnosis—many cases will evolve into other forms of spondyloarthritis.

Diagnosis of reactive arthritis rests on symptoms and signs of spondyloarthritis, including extra-articular disease, and evidence of preceding infection.

Reactive arthritis is often self-limited, but chronic forms require disease-modifying antirheumatic drugs (DMARDs) and even biologics.

Treatment of undifferentiated spondyloarthritis depends on whether axial or peripheral disease is predominant.

Two forms of spondyloarthritis will be reviewed in this chapter: reactive arthritis and undifferentiated spondyloarthritis. The other members of the spondyloarthritis group—ankylosing spondylitis, psoriatic arthritis, and arthritis associated with inflammatory bowel disease—are described elsewhere, and current thinking on common features that operate in the pathogenesis of all forms of spondyloarthritis can be found in Chapter 74.

DEFINITIONS AND TERMINOLOGY

Reactive Arthritis

The term **reactive arthritis** is sometimes used loosely, and unhelpfully, to mean “any arthritis that comes on after some kind of infection,” that is, as a “reaction” to infection. In this way, diseases such as Lyme disease and rheumatic fever are sometimes termed “reactive,” as are postviral forms of arthritis. However, this is potentially confusing; it is better to have a broad category of **postinfectious arthritis** and to reserve the term **reactive arthritis** for the arthritis that follows infection *and* shares features with other forms of spondyloarthritis.^{1,2} These include clinical features such as frequent evidence of enthesitis, in addition to arthritis, extra-articular features, particularly those involving eyes and skin, and, as required for a spondyloarthritis family member, a clear association with HLA-B27.³ Using this definition, a relatively small list of bacteria (and no viruses) are common triggers of reactive arthritis (Table 76-1), and a longer “tail” of infections have occasionally been reported

Reactive Arthritis and Undifferentiated Spondyloarthritis

J.S. HILL GASTON

as causes. These organisms principally infect the gastrointestinal and genitourinary tracts, although *Chlamydia pneumoniae* (now sometimes termed *Chlamydophila pneumoniae*) is an exception⁴⁻⁶ because it causes respiratory infection.

Another unhelpful term is **Reiter's syndrome** or Reiter's triad—consisting of urethritis, conjunctivitis, and arthritis. There are four main reasons for consigning this term to the dustbin of history. First, Hans Reiter was by no means the first to describe reactive arthritis—on this basis, reactive arthritis would be Leroy-Fiessinger-Reiter syndrome, a term that obviously lacks utility. Second, Reiter erroneously attributed the postdysenteric cases he described to spirochetal infection. Third, Reiter had an association with the Third Reich.^{7,8} Fourth, the inclusion of urethritis in Reiter's triad leads to the mistaken assumption that cases of reactive arthritis with urethritis are likely to be due to sexually acquired infection.⁹ This is not the case because urethritis is not uncommon in patients whose reactive arthritis is triggered by enteric infection, especially HLA-B27⁺ patients,¹⁰ and the cases Reiter described in World War I had arthritis associated with dysentery. Therefore, Reiter's syndrome is at best a synonym for reactive arthritis and is neither useful nor required, but the “triad” does not distinguish a clinically important subgroup of reactive arthritis.

Reactive arthritis secondary to gastrointestinal infection is sometimes bracketed with spondyloarthritis associated with inflammatory bowel disease as **enteropathic arthritis**.¹¹ However, although links between the gut and arthritis are very important pathologically, particularly in spondyloarthritis, enteropathic arthritis is really an ill-defined overlap term, which often includes other forms of arthritis that do not have classic features of spondyloarthritis but occur in relation to gastrointestinal disorders. Examples include Whipple's disease and celiac disease.

Undifferentiated Spondyloarthritis

Obvious overlap has been noted between different members of the spondyloarthritis family. By definition, patients with undifferentiated spondyloarthritis have arthritis that fails to satisfy diagnostic or classification criteria for one of the other forms. Thus, it may not be legitimate to regard undifferentiated spondyloarthritis as a separate “disease” because over time, patients often develop new features, which means that their disease is no longer “undifferentiated.” The commonest of these is development of radiographic changes in the sacroiliac joints that allow the patient to satisfy criteria for ankylosing spondylitis. This occurs in approximately 60% of patients in many series,¹² and all ankylosing spondylitis patients will pass through an “undifferentiated” phase

Table 76-1 Organisms Associated with Reactive Arthritis

Common
Gastrointestinal Pathogens
<i>Salmonella</i> species
<i>Campylobacter jejuni</i> and <i>Campylobacter coli</i>
<i>Yersinia enterocolitica</i> and <i>Yersinia pseudotuberculosis</i>
<i>Shigella flexneri</i> ; less commonly, <i>Shigella sonnei</i> or <i>Shigella dysenteriae</i>
<i>Clostridium difficile</i>
Genitourinary Pathogens
<i>Chlamydia trachomatis</i>
? <i>Mycoplasma</i> species
Respiratory Pathogens
<i>Chlamydia pneumoniae</i>
Reported
<i>Mycobacterium bovis</i> bacillus Calmette-Guérin
Enterotoxigenic <i>Escherichia coli</i> and many others in small numbers of case reports

(often termed *axial spondyloarthritis*) if seen before developing structural changes on radiographs. Likewise, patients may develop psoriasis at some point after the onset of their spondyloarthritis. In cases where there is a family history of psoriasis or features such as dactylitis, which is very common in psoriatic arthritis, the term *psoriatic arthritis sine psoriasis* is sometimes used, but if patients fail to meet diagnostic criteria for psoriatic arthritis (such as the recently devised Classification Criteria for Psoriatic Arthritis [CASPAR]¹³), they should be classified as having undifferentiated spondyloarthritis. Note that in the absence of a personal or family history of skin or nail psoriasis, patients fulfill the CASPAR criteria for psoriatic arthritis only if they have dactylitis and juxta-articular new bone formation on hand or foot radiographs, and lack rheumatoid factor. In addition, underlying inflammatory bowel disease may declare itself clinically only at some point after the onset of undifferentiated spondyloarthritis.

Finally, as discussed in the following section, it may be difficult to make a certain diagnosis of reactive arthritis, particularly when evidence of a triggering infection is absent or incomplete, resulting in significant overlap between reactive arthritis and undifferentiated spondyloarthritis—hence their being considered together in this chapter.

CLASSIFICATION CRITERIA FOR REACTIVE ARTHRITIS AND UNDIFFERENTIATED SPONDYLOARTHRITIS

Because both reactive arthritis and undifferentiated spondyloarthritis are members of the spondyloarthritis group, patients can first be identified as having spondyloarthritis by means of rather wide classification criteria. It must be recognized that classification criteria are devised to allow homogeneous sets of patients with particular features to be defined. This is critical for research studies, ensuring that different investigators report on the same set of patients. Thus classification criteria are not, and should not be used

as, diagnostic criteria; clinicians will certainly make confident clinical diagnoses for patients who fail to fulfill particular classification criteria. Nevertheless, such criteria often serve as a convenient checklist of the features that are usually present in a given disease.

The two best known classification criteria for all forms of spondyloarthritis considered together are those devised by Amor¹⁴ (Table 76-2) and the later European Spondyloarthritis Study Group (ESSG) criteria¹⁵ (Table 76-3). The Amor criteria allocate “points” to 12 features characteristic of spondyloarthritis, and classification is based on reaching a specified total score of 6 points. The ESSG criteria are applied to patients with inflammatory back pain or oligoarthritis, with the presence of additional features required for classification. The sensitivity and specificity achieved by the Amor and ESSG criteria vary in different series and inevitably depend on the population to which they are applied, but these values are usually around 80% and 90%, respectively. A more recent development in the classification of spondyloarthritis has been the separation of axial (spine and sacroiliac) inflammation from peripheral arthritis, with recognition that in different forms of spondyloarthritis, one or another of these may predominate, although with time many patients will develop both. To aid classification of axial spondyloarthritis, which traditionally requires radiographic sacroiliitis, as exemplified by the modified New York criteria for ankylosing spondylitis (AS),¹⁶ magnetic resonance imaging (MRI) changes of sacroiliitis have been included in the recently published Assessment of SpondyloArthritis international Society [ASAS] criteria¹⁷ (Table 76-4). MRI sacroiliitis is carefully defined as bone marrow edema on short tau inversion recovery (STIR) sequences, or as osteitis on T1 images with contrast medium, localized to subchondral or periarticular bone marrow. The

Table 76-2 Amor Criteria for Spondyloarthritis

Clinical Symptoms or Past History of:	Points
Lumbar or dorsal pain during the night, or morning stiffness of lumbar or dorsal spine	1
Asymmetric oligoarthritis	2
Buttock pain	1
Alternating buttock pain	2
Dactylitis of finger or toe	2
Heel pain or other well-defined enthesopathy	2
Iritis	2
Nongonococcal urethritis or cervicitis within 1 mo of arthritis onset	1
Acute diarrhea within 1 mo of arthritis onset	1
Psoriasis, balanitis, or inflammatory bowel disease	2
Radiology	
Sacroiliitis (grade ≥ 2 if bilateral; grade ≥ 3 if unilateral)	3
Genetic Background	
HLA-B27 ⁺ or family history of ankylosing spondylitis, reactive arthritis, uveitis, psoriasis, or inflammatory bowel disease	2
Response to Treatment	
Good response to NSAIDs within 48 hr, or relapse within 48 hr if NSAIDs withdrawn	2

For a definitive diagnosis of spondyloarthritis, ≥ 6 points is required; 5 points indicates probable spondyloarthritis.

NSAIDs, nonsteroidal anti-inflammatory drugs.

Table 76-3 European Spondyloarthropathy Study Group Criteria for Spondyloarthritis

For patients with:
Inflammatory spinal pain
or
Synovitis that is asymmetric or is present predominantly in the lower limbs
+ ≥1 if:
Family history of spondyloarthropathy
Psoriasis
Inflammatory bowel disease
Urethritis, cervicitis, or acute diarrhea within 1 mo of onset of arthritis
Alternating buttock pain
Enthesitis
Sacroiliitis

changes are also required to be multiple or present in at least two consecutive slices. Therefore, patients younger than 45 years of age, with at least 3 months' history of back pain or sacroiliitis on MRI (or on radiographs), plus at least one feature from the list of spondyloarthritis-associated signs and symptoms shown in Table 76-4, fulfill the criteria. In the absence of sacroiliitis, HLA-B27⁺ individuals can still be classified as having axial spondyloarthritis when two or more of these features are present. These ASAS criteria represent a recent and welcome development, but it remains to be determined what the specificity and sensitivity of MRI changes in sacroiliac joints will be when used in routine practice in nonresearch settings.

The main driver for developing the ASAS criteria for axial spondyloarthritis has been the need to define early ankylosing spondylitis without requiring radiologic changes in the sacroiliac joints. Because these often take years to develop, new criteria were required to identify, investigate, and treat patients with early ankylosing spondylitis. Nevertheless, not all patients who fulfill the criteria for axial spondyloarthritis go on to develop ankylosing spondylitis, that is, early ankylosing spondylitis is a subset of axial

spondyloarthritis. Patients who do not progress to radiographic changes or other clinical features of ankylosing spondylitis will continue to be classified as having undifferentiated spondyloarthritis.

The new ASAS criteria for axial disease are clearly useful for identifying patients with undifferentiated spondyloarthritis. In reactive arthritis, acute inflammatory back pain is common, but no studies have established the frequency of MRI-defined sacroiliitis in this disease, or of MRI-defined changes in the spine, although the latter are not used in the ASAS classification. Thus the ASAS criteria for axial spondyloarthritis are not likely to be very useful in reactive arthritis.

More relevant to reactive arthritis are the ASAS criteria for classification of peripheral spondyloarthritis, which have also been published and discussed recently^{18,19} (Table 76-5). These are applied to patients who present with arthritis, particularly asymmetric oligoarticular lower limb arthritis OR enthesitis OR dactylitis. These patients are classified as having peripheral spondyloarthritis if they have **one** additional feature from the list shown in Table 76-5. In the absence of any of these features, **two** features from an additional list are required: arthritis, enthesitis, dactylitis, inflammatory back pain, or family history of spondyloarthritis. Note that because these criteria are applied to patients who present with arthritis or enthesitis or dactylitis, this second list gives weight to the occurrence of these symptoms in combination. These criteria achieved a sensitivity of 78% and a specificity of 83%, representing a compromise between lower sensitivity and greater specificity of the Amor or ESSG criteria. How the ASAS criteria will fare in more general use remains to be seen; they were developed in a population in whom 85% were younger than age 45, and 30% had radiographic changes in sacroiliac joints that met modified New York criteria for ankylosing spondylitis, even though they did not have back pain at recruitment.

Used together, ASAS criteria for axial and peripheral spondyloarthritis should classify all those patients who have some form of spondyloarthritis (again recalling that some patients will be *diagnosed* with spondyloarthritis even though

Table 76-4 Assessment of SpondyloArthritis international Society Classification Criteria for Axial Spondyloarthritis (SpA)

For patients with back pain for ≥ 3 mo and aged <45 yr:		
Sacroiliitis on imaging	+	≥ 1 SpA feature
or		
HLA-B27	+	≥ 2 other SpA features
Sacroiliitis on imaging defined as:		
Active acute inflammation on magnetic resonance imaging highly suggestive of sacroiliitis associated with SpA		
or		
Definitive radiographic sacroiliitis according to the modified New York criteria		
SpA features comprising:		
Arthritis		
Enthesitis (heel)		
Inflammatory back pain		
Dactylitis		
Uveitis		
Psoriasis		
Inflammatory bowel disease		
Good response to nonsteroidal anti-inflammatory drugs		
Family history of SpA		
HLA-B27		
Elevated C-reactive protein

For patients with:
Peripheral arthritis (usually asymmetric, lower limb)
or
Enthesitis
or
Dactylitis
+ 1 of:
HLA-B27
Genitourinary or gastrointestinal infection
Psoriasis
Inflammatory bowel disease
Magnetic resonance imaging sacroiliitis
or
+ 2 of:
Arthritis
Enthesitis
Dactylitis
Inflammatory back pain
Family history of spondyloarthritis

Table 76-6 Proposed Definition of the Diagnosis of Reactive Arthritis

Patients can be confidently diagnosed with reactive arthritis if they have:
1. Classic clinical features:
Asymmetric oligoarthritis, predominantly lower limbs
Enthesitis
Extra-articular signs
and
Proven infection by <i>Salmonella</i> , <i>Campylobacter</i> , <i>Yersinia</i> , <i>Shigella</i> , or <i>Chlamydia</i> (whether symptomatic or not)
or
Proven infection by other organisms previously reported to be associated with reactive arthritis (e.g., <i>Clostridium difficile</i> , <i>Mycobacterium bovis</i> bacillus Calmette-Guérin)
2. Any acute inflammatory arthritis, including monoarthritis and/or axial inflammation
and
Proven infection by reactive arthritis-associated bacteria
3. Classic clinical features (as listed in No. 1)
and
Diarrhea or urethritis/cervicitis within the previous 6 wk, infection not proven

they do not meet these *classification* criteria). Of those who meet ASAS criteria, some will have documented psoriasis or inflammatory bowel disease, or radiologic sacroiliitis, and therefore can be classified as having a particular form of spondyloarthritis. The remainder will have undifferentiated spondyloarthritis or reactive arthritis. In relation to diagnosis, checking the features included in the classification criteria will allow the clinician to identify patients in whom some form of spondyloarthritis is likely, and will prompt additional clinical examination and investigations that may clarify the diagnosis or even elicit additional criteria.

In relation to reactive arthritis, there is no wholly satisfactory definition of the disease.²⁰ One practical proposal is shown in Table 76-6. In the setting of an outbreak of food poisoning, when all those known to have been infected with *Salmonella* or *Campylobacter* can be followed up, all who develop new joint symptoms can be regarded as having reactive arthritis, but inevitably this also includes patients with only arthralgias.^{21,22} Joint symptoms have a high background prevalence in the community, and it is difficult to be certain that those reported by patients following infection are genuinely related to the infection and not to pre-existing conditions that assume new prominence in the context of an infection, or to questionnaires seeking such symptoms.

In practice therefore it is best to regard only patients with new definite joint swelling, enthesitis, or inflammatory back pain as having reactive arthritis—most of these will fulfill the ASAS criteria for peripheral spondyloarthritis. In specialist rheumatology practice, as compared with community surveys, reactive arthritis patients will have clear evidence of joint inflammation and commonly enthesitis. What is often less certain is the nature of any triggering infection; the degree of certainty runs from patients with culture-proven infection with an organism previously known to cause reactive arthritis, to those who may have only a history suggesting a preceding infection or serologic evidence of infection without clinical history. A “gold standard” for reactive arthritis, requiring spondyloarthritis and unequivocal demonstration of preceding infection by

culture (or polymerase chain reaction [PCR]), would allow diagnosis of only a minority of cases, but less strict criteria inevitably result in an overlap with undifferentiated spondyloarthritis. Some surveys of patients given the latter diagnosis have produced immunologic evidence, particularly when synovial fluid T cell responses to reactive arthritis-associated organisms are measured, which suggests that a significant proportion (up to 50%) may actually have reactive arthritis.²³

INCIDENCE OF REACTIVE ARTHRITIS AND UNDIFFERENTIATED SPONDYLOARTHRTIS

Several community studies have examined reactive arthritis, mainly in Scandinavia, where HLA-B27 prevalence is high. A study in Oslo suggested an incidence of 4 to 5 per 100,000 for both *Chlamydia*-induced and enteric infection-related disease,²⁴ and similar results were reported in Finland.²⁵ Reactive arthritis following gastroenteritis has been systematically investigated by Leirisalo-Repo and colleagues, who studied populations known to have been infected with *Salmonella*, *Campylobacter*, *Yersinia*, and *Shigella* and provided follow-up by questionnaire and clinical examination to determine the incidence of new inflammatory symptoms in the joints and back, and of clinical reactive arthritis.^{21,22,26,27} Together these studies suggest that 7% to 12% of those infected develop reactive arthritis, and other studies agree with this.²⁸⁻³⁰ An incidence of 4.3 per 100,000 and 0.13 per 100,000, respectively, for *Campylobacter* and *Shigella* was reported in population studies in Finland; the low figure for *Shigella* reflected the finding that this organism was always contracted outside Finland. In other reports of outbreaks of gastroenteritis, widely differing incidences of reactive arthritis have been reported from 0 to 55%.³¹ The reasons for this are not clear but may reflect the particular serotype involved, the dose of bacteria to which subjects were exposed, and the severity of the gastroenteritis. One curious feature is the declining incidence of reactive arthritis due to *Chlamydia* infection set against a large increase in chlamydial infection generally. The explanation is unclear but may relate to the younger age group of those infected and their lack of previous exposure to related organisms.³²

The prevalence of undifferentiated spondyloarthritis has been estimated at 0.7% in one study, which identified all those meeting ESSG criteria and then removed those (≈60%) with defined forms of spondyloarthritis.³³ Because the proportion of those with undifferentiated disease who will eventually proceed to ankylosing spondylitis is approximately 60%, the prevalence of persistent undifferentiated disease is approximately 0.3%; an unknown proportion of these may have undiagnosed reactive arthritis.

CLINICAL FEATURES AND DIAGNOSIS OF REACTIVE ARTHRITIS

History

The arthritis is usually acute in onset and is normally oligoarticular, with a predilection for the lower, weight-bearing,

limbs. Mild cases picked up in surveys of populations following outbreaks of infection often have polyarthritis or polyarthralgia, but those who present clinically usually have marked synovitis with large effusions, such that septic or crystal-induced arthritis enters the differential diagnosis. A definitive diagnosis of reactive arthritis is greatly aided by two additional aspects of history: extra-articular features and preceding infection. Conjunctivitis is often transient and painless and therefore is discovered only by careful history—sometimes the red eye is noticed only by relatives. Inflammatory back symptoms or enthesitis (heel or plantar fascia pain) may be regarded as minor in comparison with the presenting joint, and a history of these features has to be specifically sought. Specific questioning is needed to elicit a history of preceding infection—the patient will not necessarily spontaneously assume a link between infection and subsequent arthritis, particularly if there is a gap of several weeks between events, although the onset of joint symptoms is rarely more than 4 weeks after infection. Gastrointestinal upset may be minor in some cases (especially with *Yersinia* infection³⁴), and a sexual history will rarely be volunteered spontaneously.

Signs

- **Joints:** Careful examination for mild involvement of joints other than the presenting ones is important, particularly in apparent monoarthritis; discovery of even mild synovitis of a proximal interphalangeal (PIP) or wrist joint, in addition to a grossly swollen knee, greatly decreases the likelihood of septic arthritis.
- **Entheses:** Major entheses should be examined for signs of inflammation (Figure 76-1); loss of weight bearing due to ankle or knee arthritis may mean that the patient is unaware of significant Achilles tendinitis or plantar fasciitis. The Maastricht Ankylosing Spondylitis Enthesitis Score (MASES) provides a helpful list of 13 major entheses: first and fourth costochondral joints, L + R; anterior and posterior iliac spines, L + R; iliac crest, L + R; fifth lumbar spinous process; and Achilles tendon insertion, L + R, which should be checked.³⁵ Missing from this list but readily examined is the calcaneal plantar fascia insertion. Alternatively,

Figure 76-1 Enthesitis of right Achilles tendon.

Figure 76-2 Dactylitis of the right middle finger.

the Mander index may be used.³⁶ Tendinitis may combine with arthritis to produce characteristic dactylitis in fingers or toes (Figure 76-2).

- **Extra-articular disease:** The characteristic skin rash associated with reactive arthritis, keratoderma blennorrhagica (Figure 76-3), should be sought on soles and palms—again, the former may not be evident to the patient. Histologically, the rash is identical to psoriasis, but skin biopsy is rarely required to establish the nature of the rash. The other typical associated rash is circinate balanitis on the glans penis (Figure 76-4); this also needs to be specifically sought, particularly in uncircumcised males. Erythema nodosum is seen in *Yersinia* infection but rarely in other reactive arthritis-associated infections. Mouth or palatal ulcers are often painless and may not be reported by the patient. Conjunctivitis sometimes is still present when the patient is first seen by a rheumatologist, but ongoing pain or visual disturbance raises the possibility of uveitis and requires full ophthalmologic assessment.

Figure 76-4 Circinate balanitis.

Investigations

Blood Tests

Inflammatory markers (erythrocyte sedimentation rate [ESR], C-reactive protein [CRP]) will be raised, often impressively so, with CRP greater than 100 mg/L; white cell count and differential will usually show neutrophilia; serum urate is useful in relation to an alternative diagnosis, and glucose should be measured to allow interpretation of synovial fluid glucose.

Tests on Synovial Fluid

Because the differential diagnosis of reactive arthritis very commonly includes septic arthritis or crystal-induced disease, synovial fluid should be aspirated whenever possible. Cell count, bacteriologic culture, glucose levels, and examination under polarizing microscope for crystals are needed to exclude septic and crystal arthritis.

In a research setting, measurement of synovial T cell recognition of triggering organisms or specific bacterial antigens as proliferation (usually uptake of ^3H -thymidine) or cytokine production has been informative. It is also possible to examine cells in synovial fluid using flow cytometry³⁷⁻⁴⁰ for surface phenotype and intracellular cytokine staining. Recently, increased numbers of CD4⁺ T lymphocytes producing interleukin (IL)-17 have been described in reactive arthritis synovial fluid.⁴¹ However, currently, none of these research tests can be used diagnostically. They are unlikely to ever achieve high specificity because production of pro-inflammatory cytokines such as IL-17 or interferon- γ is common to various forms of inflammatory arthritis. In addition, memory T cells are recruited to inflamed joints so that, for example, a patient with active RA and an incidental *Chlamydia* infection is likely to have *Chlamydia*-specific T cells in the synovial fluid and tissue. Nevertheless, when there is a high pretest probability of reactive arthritis (i.e.,

the patient has signs and symptoms consistent with this diagnosis), the finding of marked responses to one particular reactive arthritis-associated organism is likely to be relevant diagnostically and may lead to confirmation of the nature of the triggering infection by other means.

Microbiology

Culture and Other Means of Detecting Bacteria. The aim is to gather evidence to implicate a reactive arthritis-associated organism. For gastrointestinal infection, stool culture should be carried out; organisms such as *Salmonella* and *Yersinia* may persist in the gut for several weeks after gastroenteritis has resolved. *Yersinia* has the unusual property of growing at 4° C, which allows improved detection of the organism by maintaining the stool sample at 4° C for 24 to 48 hours prior to culture; microbiology laboratories should be informed that *Yersinia* infection is being considered to allow them to do this. Stool culture for *Yersinia* is also appropriate in patients without gastrointestinal symptoms because symptoms are often mild in infection with this organism. For genitourinary infection, swabs should be obtained from the urethra or vagina for culture of *Chlamydia trachomatis* and, if indicated, from the throat and rectum. However, in view of the difficulty involved in culturing chlamydiae, nucleic acid amplification techniques (ligase chain reaction [LCR], PCR) are generally preferred and can be performed on urine samples or by self-administered swabs, both of which are acceptable to patients. Use of PCR to identify *Chlamydia* in synovial fluid has not yet been developed sufficiently.⁴² PCR is also helpful in establishing a diagnosis of *Chlamydia pneumoniae* infection when arthritis is seen in association with respiratory tract infection. The presence of chlamydiae can be detected in urine or sputum by means of an enzyme-linked immunosorbent assay (ELISA) to detect chlamydial lipopolysaccharide (LPS).

Serology. Although culture or direct demonstration of the organism is preferred, in some circumstances serology can provide reliable evidence of a preceding infection. Its effectiveness depends very much on the frequency of infection in the community and therefore on the proportion of subjects with pre-existing antibodies. For *Salmonella* species, and increasingly for *Campylobacter*, antibodies are commonly detected in healthy subjects because of a high level of community exposure to these organisms. In these cases therefore, diagnosis will rest, at best, on an increased titer of pathogen-specific antibodies in acute and convalescent sera. Because patients may present to rheumatologists in the convalescent phase, as far as the triggering infection is concerned, this substantially decreases the utility of serology in diagnosing these infections. In contrast, infection with *Yersinia* or *Shigella* is not prevalent in Western societies, so that detection of specific antibodies carries greater significance even if immunoglobulin (Ig)M antibodies or a fourfold increase in titer cannot be demonstrated. For detection of chlamydial infection, serology generally has not proved reliable. Micro-immunofluorescence tests can be carried out, in which dilutions of sera are applied to multi-well slides containing organisms; this is regarded as the “gold standard” for *Chlamydia* serology. However, again the prevalence of antibodies in the population is high, particularly for

C. pneumoniae in older subjects. Individual recombinant chlamydial antigens have been used to devise additional serologic tests, but none has yet been established for general use.

HLA-B27 Testing

Testing for HLA-B27 generally is not required to make the diagnosis of reactive arthritis. Although more severe cases such as those seen in secondary care are strongly associated with HLA-B27 (70% to 80% of cases are positive), the percentage of positivity is much less in milder cases and is highly variable in different published series. However, HLA-B27 testing is worthwhile because it may identify patients with an increased likelihood of persistent disease, in whom early introduction of disease-modifying antirheumatic drugs (DMARDs) would be indicated (see later).

Imaging

Radiographs of affected joints are unlikely to be useful diagnostically when reactive arthritis presents, but baseline films are useful for future management. Imaging techniques that can identify inflammation of affected joints or entheses are what is required; the choice lies between ultrasound (particularly power Doppler studies), scintigraphy, and MRI. As noted previously, MRI may reveal sacroiliitis or other evidence of axial involvement but is not required for joints with clinically obvious synovitis—the norm in reactive arthritis. Power Doppler ultrasonography appears promising for detecting enthesitis but is not without difficulties in interpretation.⁴³⁻⁴⁵ This technique may also reveal enthesitis in rheumatoid arthritis, thereby producing difficulties for the ASAS classification criteria, but this enthesitis is usually noted in relation to nearby synovitis rather than as the predominant inflammatory lesion. Likewise, scintigraphy did not perform particularly well in detecting sacroiliitis in a population with chronic back pain⁴⁶; it might perform better in young patients with sacroiliitis due to reactive arthritis, because the background prevalence of abnormalities in healthy young controls is likely to be much lower.

TREATMENT OF REACTIVE ARTHRITIS

Control of Symptoms

Most patients (80% to 90%) will have self-limiting disease, which does not require disease-modifying drugs. Symptomatic measures include full-dose nonsteroidal anti-inflammatory drugs (NSAIDs), preferably long-acting, with the choice between selective and nonselective drugs dependent on the patient's risk of gastrointestinal bleeding versus cardiovascular disease; in young patients, the former predominate, so there is a preference for agents such as etoricoxib.⁴⁷ Additional analgesics may be required. Intra-articular corticosteroids are very useful when infection has been confidently excluded, and injection of enthesitis may also be required with avoidance of the Achilles tendon insertion, in view of the tendency of this tendon to rupture. In patients with severe disease and systemic features, parenteral or short-course oral steroids may be used. Patients

require physiotherapy to maintain muscle bulk and range of movement. Informal psychologic support is often crucial because, although the disease is self-limiting, it commonly takes 6 to 12 months to remit. In a young, previously fit patient, this is perceived as a major medical event, curtailing many sporting and leisure activities, and sometimes interfering with employment.

Disease-Modifying Drugs

Few controlled trials have examined the use of DMARDs in reactive arthritis. Such patients were included in a trial of sulfasalazine in spondyloarthritis,⁴⁸ and sulfasalazine was also tested in reactive arthritis.⁴⁹ The natural tendency of spontaneous remission makes it difficult for investigators to conduct trials to determine the effectiveness of DMARDs, but sulfasalazine showed effectiveness in 62% of reactive arthritis patients as compared with 48% in placebo. In undifferentiated spondyloarthritis, sulfasalazine was reported not to be effective, although an unexpected effect on axial symptoms, but not peripheral arthritis, was recorded.⁵⁰ This result is at variance with other findings.^{51,52} When should DMARDs be introduced in reactive arthritis? Patients who have severe, persistent disease or recurrent disease, particularly those who are HLA-B27⁺, are candidates for the early introduction of DMARDs. However, even patients with very severe presentation can settle rapidly with NSAIDs and intra-articular steroids, so only those who are responding slowly or whose disease flares significantly after an initial response would justify introduction of DMARDs within the first 3 months of disease. Those who relapse after having responded well initially are also likely to require DMARDs. The risk-benefit ratio of sulfasalazine is favorable, and the drug is a logical choice in cases triggered by enteric infection. Patients who fail sulfasalazine can progress to methotrexate or leflunomide, or a combination of the two. Note however, that none of these recommendations on the use of DMARDs has been properly tested in controlled trials. In view of the favorable course in most patients, there is reluctance to test early use of drugs such as methotrexate in the way that is now commonplace in rheumatoid arthritis (RA).

Biologics

Only in rare cases have biologics such as tumor necrosis factor (TNF)-blocking agents⁵³⁻⁵⁵ or tocilizumab⁵⁶ been used in reactive arthritis, although they appear to be effective. They have not been reported to be associated with recrudescence of infection—an important consideration in view of evidence for persistence of triggering organisms such as *Chlamydia*^{57,58} or *Yersinia*.⁵⁹ In light of reports of increased numbers of T helper (Th)17 cells in reactive arthritis joints and genetic evidence implicating the IL-17 axis in spondyloarthritis, rational future use of biologics might suggest the use of inhibitors of IL-23—ustekinumab, which recognizes the shared IL-12/23 p40 subunit and is effective in psoriasis,^{60,61} or a IL-23-specific antibody targeting the p19 unit, currently in trial, or IL-17 itself. IL-6 and IL-1 are also implicated in generating Th17 cells,⁶² and the efficacy of tocilizumab (in a single case report) may reflect an effect on the generation of Th17 cells.

Antibiotics

By definition, the joint in reactive arthritis is sterile, so there is no *prima facie* case for treatment of arthritis with antibiotics. Obviously, chlamydial infection in the genitourinary tract requires conventional treatment to avoid damage and scarring, particularly in females; *Chlamydia pneumoniae* respiratory tract infection also needs treatment. In general, food poisoning does not require antibiotics, although ciprofloxacin is often used to reduce symptom duration.⁶³

In relation to arthritis, the use of prolonged courses of antibiotics has been advocated in view of increasing evidence of persistence of the organism, within the joint and elsewhere, despite adequate antibiotic treatment of the primary infection; this applies particularly to chlamydia infection. Several placebo-controlled trials have examined the effects of prolonged courses of antibiotics (3 to 6 months), which are effective with reactive arthritis-associated bacteria (tetracycline, ciprofloxacin, and azithromycin) and with outcome in reactive arthritis.⁶⁴⁻⁶⁸ For disease due to enteric infection, the results are uniformly negative. In an early trial, post hoc subgroup analysis suggested a beneficial effect of prolonged lymecycline in *Chlamydia*-induced disease⁶⁴; an effect of prolonged antibiotics on *Chlamydia*-induced arthritis was not confirmed in subsequent trials,^{68,69} although some studies may not have had sufficient *Chlamydia*-induced cases. A recent and controversial study used a combination of antibiotics, rifampicin with doxycycline, and azithromycin, which were chosen to be effective against persistent, slowly dividing organisms; investigators reported effectiveness in *Chlamydia*-induced reactive arthritis, including in patients with long-standing disease (mean duration, 10 to 14 years).^{70,71} Seventeen of 27 antibiotic-treated patients achieved the trial end point compared with 3 of 15 receiving placebo, and treatment was associated with clearance of chlamydiae as detected by PCR. The trial involved relatively small numbers, and the findings require confirmation.

OUTCOME IN REACTIVE ARTHRITIS

A vast majority of patients with reactive arthritis make a full recovery with no chronic joint damage, although in more severe cases, 12 to 18 months may be required for complete resolution of symptoms. Remaining patients have progressive spondyloarthritis with relapses and involvement of new joints and entheses in the absence of any evidence of re-infection, and often increasing prominence of axial symptoms and radiographic changes of ankylosing spondylitis.⁷² HLA-B27 is the main factor predisposing to chronicity or recurrence in reactive arthritis and is worth testing for this reason. It is possible that polymorphisms in other genes,⁷³ including those that influence susceptibility to AS,⁷⁴ will also affect outcome in reactive arthritis, but this remains to be tested. Of course it may be argued that HLA-B27⁺ patients are predisposed to both reactive arthritis and other forms of spondyloarthritis, and therefore might develop two diseases rather than reactive arthritis evolving into ankylosing spondylitis, but the clinical impression suggests evolution rather than development of a new disease.

Severe arthritis (large effusions, multiple joints, and very high levels of CRP and ESR) does not necessarily correlate with persistent disease, but complete recovery will usually take longer (6 to 12 months) compared with milder disease. Young active patients require counseling to prepare them for this.

DIAGNOSIS AND TREATMENT OF UNDIFFERENTIATED SPONDYLOARTHRITIS

Because, as discussed previously, undifferentiated spondyloarthritis by definition is not a “specific” disease, a detailed account of its diagnosis and treatment is somewhat redundant.

Diagnosis

Briefly, patients present rheumatologically with arthritis or enthesitis, or dactylitis, which is itself a combination of these conditions. In such cases, the diagnosis will be based on additional features of spondyloarthritis, as detailed in the ASAS classification criteria for axial or peripheral arthritis. An algorithm for diagnosing axial disease on this basis has been published.⁷⁵ Every attempt should be made to rescue the patient from the undifferentiated diagnosis to a more distinct form of spondyloarthritis, but this will not always be possible, especially in those with early disease and in a percentage of those with long-standing disease.

Investigations

These have already been detailed in relation to reactive arthritis. In cases with predominantly axial disease, inflammatory markers may not be elevated.

Treatment

Patients with undifferentiated spondyloarthritis will have different combinations of axial and peripheral disease. Where axial disease predominates, management will most resemble that for ankylosing spondylitis. Patients usually will require full-dose NSAIDs (a good response to these reinforces the diagnosis), axial symptoms are generally refractory to conventional DMARDs, and a proportion of patients will require treatment with biologics, particularly anti-TNF, when symptom control with NSAIDs proves inadequate.^{76,77} An important research question is whether early intervention with anti-TNF will prevent progression of undifferentiated spondyloarthritis to ankylosing spondylitis, that is, whether the “window of opportunity” concept leading to early aggressive treatment of rheumatoid arthritis might also apply to ankylosing spondylitis. Peripheral disease is managed in a similar fashion to psoriatic arthritis, or reactive arthritis in its more chronic, established form, with the use of DMARDs—sulfasalazine, methotrexate, and leflunomide, given individually or in combination. In the absence of psoriasis or a family history of psoriasis, hydroxychloroquine can be used, often as an add-on to another more powerful DMARD. Finally, the antibiotic regimen recently reported to be effective in *Chlamydia*-induced

reactive arthritis was first tested in undifferentiated arthritis on the assumption that it might be related to *Chlamydia*⁷⁸; findings showed some efficacy.⁷⁹

UNANSWERED QUESTIONS AND FUTURE RESEARCH

1. How Many Patients Currently Classified as Undifferentiated Spondyloarthritis Actually Have Reactive Arthritis?

Answering this question requires better diagnostic techniques. For *Chlamydia*-induced reactive arthritis, detection of bacteria-specific mRNA has been reported, even in late disease. However, the problems of using PCR with high levels of amplification while avoiding contamination have not been fully resolved. Given that chlamydiae might traffic to any inflamed joint, and therefore may be identified by PCR in, for example, RA joints, it may be that a specific transcript or set of transcripts will be associated with bacterial persistence in the joint, which drives reactive arthritis. Equally, a synovial tissue or fluid gene expression “signature” characteristic of reactive arthritis may exist (better still, a peripheral blood signature) and may be used for diagnosis. This would be particularly useful in reactive arthritis triggered by enteric organisms because bacteria-specific mRNA in the joints of these patients has only occasionally been reported.

2. Do Antibiotics Have Any Role in the Treatment of Established Reactive Arthritis?

This question has been re-opened, at least for *Chlamydia*-induced arthritis, by recent data reporting successful treatment with combinations of azithromycin or tetracycline and rifampicin. These observations need to be repeated and expanded. A positive result would lead to exploration of the same combinations in other forms of reactive arthritis.

3. What Is the Role of HLA-B27 in Inducing Susceptibility to Reactive Arthritis, and What Other Genes Influence Susceptibility?

These questions are generic for our understanding of the pathogenesis of spondyloarthritis. They have rightly been addressed initially in ankylosing spondylitis, where the incidence of HLA-B27 is very high and case definitions can be well controlled. Mechanisms for the mode of action of HLA-B27, which emerge from these studies, can be re-examined in reactive arthritis, where an interaction with the consequences of intracellular infection might be expected. Although this was initially seen in terms of HLA-B27 presenting “spondylitogenic” peptides from reactive arthritis-associated bacteria, other mechanisms involving homodimeric B27 heavy chains or induction of the unfolded protein response may present opportunities for interactions with bacteria. As other genes associated with ankylosing spondylitis are identified, they need to be tested in reactive arthritis. There is a need therefore to establish cohorts of reactive arthritis patients in which the diagnosis is certain so that accurate genetic work can be done.
